# CONIC SECTIONS.

CONIC SECTIONS are curves formed by the intersection of a cone and plane. The conic sections are the ellipse, the parabola, and the hyperbola. The ellipse is a closed curve, the parabola is an open curve, and the hyperbola is an open curve with two branches. The conic sections are named after the Greek word for cone, which is 'konos'.

## Volume 21 SPELMAN TO TIMMINS

**SPELMAN, SIR HENRY** (c. 1564–1641), English antiquary and historian whose *Concilia, Decreta, Leges, Constitutiones, in re Ecclesiarum orbis Britannici* was the first systematic compilation of church documents, was born about 1564 at Congham, Norfolk. Educated at Trinity College, Cambridge, and Lincoln's Inn, London, he was M.P. for Castle Rising in 1593 and 1597, sheriff of Norfolk in 1604, M.P. for Worcester in 1625, and served on several royal commissions. A student of antiquity, he belonged, with William Camden and Sir Robert Cotton, to the Society of Antiquaries, which he attempted to revive in 1614, and he endowed a lectureship in Anglo-Saxon at Cambridge. He died in London in 1641.

Spelman was the author of ecclesiastical and legal histories, most of which were published posthumously. His first religious work, *De non temerandis ecclesiis; a Tracte Of the Rights and Respect Due Unto Churches* (1613), was the foundation of his well-known *History and Fate of Sacrilege* (1698); but his chief work was his history of the church, *Concilia, Decreta, Leges, Constitutiones, in re Ecclesiarum orbis Britannici* (vol. 1, 1639; vol. 2, ed. by C. Spelman, 1664). Among his polemical writings were *De Sepultura* (1641) and *Tithes Too Hot to be Touched* (1646), and he also made a glossary of ancient legal terms, *Archæologus* (part 1, 1626; part 2, ed. by W. Dugdale, 1664). (R.D. C. G.)

**SPEMANN, HANS** (1869–1941), German embryologist and Nobel laureate, was born at Stuttgart on June 27, 1869. In 1891 he began the study of medicine and attended the universities of Heidelberg, Munich, and Würzburg but finally graduated in zoology, botany, and physics. From 1894 to 1908 he worked at the Zoological Institute of Würzburg and was then appointed professor of zoology and comparative anatomy at Rostock. In 1914 he became director of the Kaiser Wilhelm Institute for Biology in Berlin, and from 1919 until his retirement in 1935 he held the chair of zoology at Freiburg im Breisgau.

Spemann was awarded the Nobel Prize for physiology and medicine in 1935 for the discovery of what is known as the "organizer effect" in embryonic development (see EMBRYOLOGY AND DEVELOPMENT, ANIMAL: *Experimental Embryology*). He stated, "the beginnings of a human individual do not differ essentially from those of an echinoderm." His concept of organizers was based upon a lifetime of research into the early development of

the common newt. Much of his success was due to his intense concentration on this seemingly narrow field; but apart from this he had the controlled imagination of the true scientist and was a master of the techniques of microsurgery. Spemann's experiments showed that, in the earliest stages, the fate of the embryonic parts has not been determined; thus, if a piece of presumptive skin tissue is excised and transplanted into an area of presumptive nervous tissue, it will form nervous tissue, not skin. These researches threw new light not only on the normal processes of development and growth but also on the genesis of various congenital abnormalities of the human body. He gave a masterly summary of his researches in his Croonian lecture before the Royal Society (1927) and in his Silliman lectures at Yale (1935). He died at Freiburg im Breisgau on Sept. 12, 1941. (W. J. BP.)

**SPENBOROUGH**, an urban district in the West Riding of Yorkshire, Eng., 6 mi. SE of Bradford. Pop. (1961) 36,417. Area 12.9 sq.mi. It is a manufacturing district in the Spen valley. The textile industry is the chief one, including carpets, rayon and woolen materials. The manufacture of machinery and sheet-metal goods is important. The urban district was formed in 1915 and combined the three former urban districts of Cleckheaton, Gomersal, and Liversedge. In 1937 its area was enlarged by the addition of the urban districts of Birkenshaw and Hunsworth and the rural district of Hartshead and part of Clifton. Brighouse and Spenborough were formed into a parliamentary borough in 1948, returning one member.

**SPENCER, HERBERT** (1820–1903), English philosopher, achieved an influential synthesis of knowledge, advocating the pre-eminence of the individual over society and of science over religion. He was born in Derby on April 27, 1820. His father, William George Spencer, was a schoolmaster, and his parents' dissenting religious convictions inspired Herbert with that spirit of non-conformity which continued active in him after he had abandoned the Christian faith. He declined an offer from his uncle, the Rev. Thomas Spencer, to send him to Cambridge, and his higher education was largely the result of his own reading, which was chiefly in the natural sciences. After a few months as a schoolteacher he became a railway engineer in 1837 and worked on the Birmingham and Gloucester railway until its completion in 1841.

In 1842 he contributed some letters (republished as a

pamphlet, *The Proper Sphere of Government*, 1843) to the *Non-conformist*, in which he argued that it is the business of governments to uphold natural rights and that they do more harm than good when they go beyond this. After some association with progressive journalism through such papers as the *Zoist* (devoted to mesmerism and phrenology) and the *Pilot* (the organ of the Complete Suffrage union), Spencer became in 1848 a subeditor of the *Economist*. In 1851 he published *Social Statics* (reissued with preface by F. Neilson, 1955), which contains in embryo most of his later views. He here argues in favour of an extreme form of economic and social *laissez faire* and describes progress as "not an accident but a necessity." About 1850 Spencer made the acquaintance of G. H. Lewes and Marian Evans (George Eliot). His philosophical conversations with the latter led some of their friends to expect that they would marry; but in his *Autobiography* (1904) Spencer says that there was never any such desire on his part, much as he admired Miss Evans' intellectual powers. Other friends were T. H. Huxley and J. S. Mill. In 1853 Spencer received a legacy from his uncle and, relying on this, resigned his position with the *Economist*.

Having published the first part of *The Principles of Psychology* in 1855, Spencer in 1860 issued a prospectus and obtained promises of subscriptions for a comprehensive work, *The Synthetic Philosophy*, which was to include, besides the already published *Principles of Psychology*, volumes on first principles and on biology, sociology and morality. *First Principles* was published in 1862, and between then and 1896, when the third volume of the *Principles of Sociology* appeared, the task was completed. In order to prepare the ground for *The Principles of Sociology*, Spencer, in collaboration with David Duncan and others, started in 1873 a series of works called *Descriptive Sociology*, in which information was provided about the social institutions of various societies, both primitive and civilized. The series was interrupted in 1881 because of lack of public support. Spencer was a close friend of Richard Potter, chairman of the Great Western Railway company, and thus became a friend and adviser of his children, one of whom was Beatrice Potter (who later became Beatrice Webb). She frequently visited Spencer during his last illness and left a sympathetic but sad record of his last years in *My Apprenticeship* (1926). Spencer died on Dec. 8, 1903, at Brighton, leaving a will by which trustees were set up to complete the publication of the *Descriptive Sociology*. Further volumes were written by such authorities as Sir W. Flinders Petrie and J. P. Mahaffy; the series eventually amounted to 19 parts (1873-1934).

Spencer was one of the most argumentative and most discussed English thinkers of the late Victorian period. He vigorously advocated the scientific or naturalistic view of the world against supernaturalism. He was, too, the prophet of evolution and of progress. As a liberal, he upheld the doctrine of *laissez faire* in a most uncompromising form. As a student of society, he urged the importance of examining social phenomena in a scientific way and endeavoured to do this himself. All these aspects of his thought were believed by him to form a coherent and closely ordered system. Science and philosophy, he held, gave support to individualism and progress. It is natural to cite him, therefore, as the great exponent of Victorian optimism, but it should also be noticed that he was by no means unaffected by the pessimism which from time to time clouded the Victorian confidence. Evolution, he taught, would be followed by dissolution, and individualism would come into its own only after an era of socialism and war.

**The Synthetic Philosophy in Outline.**—According to Spencer, philosophy is a synthesis of the fundamental principles of the special sciences, a sort of scientific *summa* to replace the theological systems of the middle ages. "Science is *partially-unified* knowledge; philosophy is *completely-unified* knowledge" (*First Principles*, 37). Spencer thought of unification in terms of development, and his whole scheme was suggested to him by the evolution of biological species. In an article entitled "The Development Hypothesis" (1852-54) he rejected the notion of special creation, and in "Progress: its Law and Cause" (1857) he applied the idea, borrowed from K. E. von Baer, that biological development in the individual is from the homogeneous to the hetero-

geneous to the evolution of the solar system, of animal species, of human society and of industry, art, language and science. It should be noticed that Spencer published his idea of the evolution of biological species before the views of Charles Darwin and Alfred Russel Wallace were known; but Spencer thought at that time that this evolution was caused by the inheritance of acquired abilities whereas Darwin and Wallace attributed it to natural selection. Spencer later accepted the theory that natural selection was one of the causes of biological evolution and himself coined the phrase "survival of the fittest" (*Principles of Biology* [1864], vol. i, p. 444). But he continued to hold that alterations caused in the organism of a particular animal by forces external to it may be passed on by it to its descendants (pp. 269-270). Furthermore, he did not think that the inheritance of acquired characteristics or the survival of the fittest were ultimate principles of evolution. In his view the principle of change from homogeneity to heterogeneity was more important than either and was itself a consequence of principles still more fundamental. In *First Principles* his argument is that there is a fundamental law of matter, which he calls the law of the persistence of force, from which it follows that nothing homogeneous can remain as such if it is acted on, because any external force must affect some part of it differently from how it affects other parts and hence cause difference and variety to arise. From this it follows that any force that continues to act on what is homogeneous must bring about an increasing variety. This law of the multiplication of effects is, in Spencer's view, the clue to the understanding of all development, cosmic as well as biological. He holds that an unknown and unknowable absolute force is continuously operating on the material world and producing variety, coherence, integration, specialization and individuation. Gases concentrate to form planets; the earth becomes more variegated and gives birth to such simple animals as the amoeba; man evolves from less complex species and at first lives in undifferentiated hordes; various social functions are developed so that there are priests, kings, scholars, workers, etc.; poetry splits off from music and painting from drama so that a diversity of arts arises; and knowledge itself is differentiated into the various sciences. But when the final stage of integration has been reached, Spencer holds, dissolution must necessarily ensue, so that the variety and coherence of the world will lapse into quiescence once more. "And have we thus to contemplate," he asks, "as the outcome of things, a boundless space holding here and there extinct suns, fated to remain for ever without further change?" (*First Principles*, 1862). His answer is that this may be, but that perhaps a new form of integration will then commence which, after reaching an equilibrium, will itself decay and be followed by new evolutions and dissolutions in an infinite alternation.

**Sociology and Social Philosophy.**—Spencer applies his general evolutionary scheme to human society. Indeed, it was from reflection on human society that he conceived it, as can be seen, in *Social Statics*, where social evolution is held to be a process of increasing "individuation." Human societies, then, evolve from undifferentiated hordes, by means of increasing division of labour, into complex civilizations. Spencer believed that primitive men were smaller, less intelligent and more emotional than civilized men; that light was thrown on their mentality by study of children in civilized societies; that their religion arose from belief in ghost souls seen in dreams, so that worship was originally directed toward the spirits of dead ancestors; that civilized religions were all more or less elaborate variations on this primitive theme; and that the fundamental sociological classification was between military societies, in which co-operation was secured by force, and industrial societies, in which co-operation was voluntary and spontaneous. The word "industrial" is used here not in the sense of "technologically developed"—for Spencer gives instances of extremely simple societies such as the Todas to illustrate his meaning—but to designate societies chiefly concerned with producing for their members' needs by peaceful and voluntary co-operation. Military societies are ruled by warlike chiefs who maintain themselves in power by arms and superstition; in them women are depressed in status and often forced to do the most

burdensome work; and there is an hierarchical organization in which each individual is expected to know and to keep his place. Industrial societies are the reverse of all this, although, if they become involved in war, they have to adopt the military, hierarchical organization.

Evolution is not the only biological conception that Spencer applies in his sociological theories. He also made a detailed comparison between animal organisms and human societies. In both there is a regulative system (the central nervous system in the one, government in the other), a sustaining system (alimentation in the one case, industry in the other) and a distributing system (veins and arteries in the animal body; roads, telegraphs, etc., in the social organism). The great difference, however, between an animal and a social organism is that whereas in the former there is one consciousness relating to the whole, in the latter consciousness exists in each member only and there is no consciousness relating to the whole. Society as a whole has no mind. At this point Spencer abandons description and theory in order to conclude that society exists for the benefit of its members, and not they for its benefit.

This individualism is the key to all of Spencer's work. His contrast between military and industrial societies is a contrast between types of order which he considered bad and those which he considered good. In industrial society coercion and regimentation are at a minimum, and the order achieved, although—indeed because—not planned by anyone, is delicately adjusted to the needs of all parties. In *The Man versus the State* (1884) Spencer says that the Tories support a military and Liberals an industrial social order, but he thought that the Liberals of the latter half of the 19th century were, with their legislation on hours of work, liquor licensing, sanitation, education, etc., developing a "New Toryism" and preparing the way for a "coming slavery." "The function of Liberalism in the past was that of putting a limit to the powers of kings. The function of true Liberalism in the future will be that of putting a limit to the powers of Parliaments."

In his emphasis on variety and differentiation Spencer was unwittingly repeating, in a 19th-century idiom, the metaphysics of liberalism which Spinoza and Leibniz had adumbrated in the 17th century. Spinoza had maintained that "God or Nature" has an infinity of attributes in which every possibility is actualized; and Leibniz had argued that the perfection of God is exhibited in the infinite variety of the universe. Neither of these philosophers believed that time was an ultimate feature of reality. Spencer, however, combined a belief in the reality of time with a belief in the eventual actualization of every possible variety of being. He thus gave metaphysical support to the liberal principle of variety according to which a differentiated and developing society is preferable to a monotonous and static one.

Spencer's attempt to synthesize the sciences showed a sublime audacity which was not repeated because the intellectual specialization which he welcomed and predicted increased beyond his expectations. His sociology, although it gave an impetus to the study of society, was superseded as a result of the development of social anthropology since his day and was much more concerned with providing a rationale for his social ideals than he himself appreciated. Primitive men, for example, are not the childlike emotional creatures that he thought them to be, nor is religion to be explained only in terms of the souls of ancestors. When T. H. Huxley said that Spencer's idea of a tragedy was of "a deduction killed by a fact," he called attention to the system-building feature of Spencer's work which led him to look for what confirmed his theories and to ignore or to reinterpret what conflicted with them.

Spencer's *Synthetic Philosophy* finally comprised the following books: *First Principles* (1862), rev. ed. (1900); *The Principles of Biology*, 2 vol. (1864–67), rev. ed. (1898–99); *Principles of Psychology*, 2 vol. (1855, 1872), 4th ed. (1899); *The Principles of Sociology*, 3 vol. (1876–96); and *The Principles of Ethics*, 2 vol. (1892–93). Other important books are: *Essays: Scientific, Political and Speculative*, 3 series (1857–74), final ed. 3 vol. (1891); *Education: Intellectual, Moral, Physical* (1861); *The Study of*

*Sociology* (1873; 1961); *The Nature and Reality of Religion* (1885), withdrawn from publication; *Facts and Comments* (1902). His *Autobiography* (2 vol.) was published posthumously in 1904. *First Principles* (6th ed.) was reissued in 1937.

**SPENCER, JOHN CHARLES SPENCER, 3RD EARL** (1782–1845), English statesman, better known as **VISCOUNT ALTHORP**, played a major part in securing passage of the Reform Act of 1832. The eldest son of George John, who succeeded as 2nd earl in 1783, he was born at Spencer House, London, on May 30, 1782, and was educated at Harrow and at Trinity College, Cambridge. He represented Okehampton (1804–06), St. Albans (1806), Northamptonshire (1806–32), and Northamptonshire South (1833–34). When Earl Grey's administration was formed in November 1830, Lord Althorp became chancellor of the exchequer and leader of the House of Commons. His first budget (February 1831) was a failure, but this was soon forgotten in the struggles over the Reform Bill, which he and Lord John Russell twice piloted successfully through the Commons. "Althorp carried the bill," said a leading opponent, Sir Henry Hardinge, "his fine temper did it."

Althorp was neither eloquent nor nimble witted; he owed his ascendancy over the Commons to his courage, integrity, and judgment. He was able to gauge feeling among the squires who predominated in the House of his day, for he shared their tastes and habits of mind. In Sir Robert Peel, then leading the opposition, he faced a redoubtable parliamentarian, and his own following of Whigs, Radicals, and Irish was ill mixed and hard to manage; yet his success as leader was complete. "He became," wrote the diarist Charles Greville, a severe contemporary judge, "the very best leader of the . . . Commons that any party ever had . . . The whole House liked him, his own party followed him with devoted attachment."

Lord Althorp retired from politics when called to the House of Lords in November 1834 on his father's death. His removal from the Commons was the occasion of William IV's dismissal of Viscount Melbourne's ministry. He was the first president of the Royal Agricultural Society (founded 1838) and a notable short-horn cattle breeder. He died at Wiseton Hall, Nottinghamshire, on Oct. 1, 1845.

For contemporary opinions see C. C. F. Greville, *Memoirs*, 1st series, vol. iii (1875) and 2nd series, vol. ii (1885); A. Aspinall (ed.), *Three Early Nineteenth Century Diaries* (1952). (M. G. B.; X.)

**SPENCER, SIR STANLEY** (1891–1959), English painter of religious subjects, landscapes, portraits, and social satires, was born at Cookham, Berkshire, on June 30, 1891, son of W. Spencer, organist. He studied at the Slade School of Art and began to exhibit at the New English Art Club. During World War I he served in the Royal Army Medical Corps in Macedonia and painted "Travoy's Arriving with Wounded" for the Imperial War Museum. In 1932 he completed "Resurrection of the Soldiers" and scenes from army life in the chapel at Burghclere, Hampshire. "Christ Carrying the Cross" (1920), "Resurrection" (1927), representing the dead rising from their tombs in Cookham churchyard, and a later "Resurrection" (1950) are at Tate Gallery, London. He also painted highly finished landscapes and humorous comments on the absurdity of human behaviour. He was elected a royal academician in 1950 and knighted in 1959. He died at Taplow, Buckinghamshire, on Dec. 14, 1959.

**BIBLIOGRAPHY.**—*Stanley Spencer Retrospective Exhibition Catalogue*, Tate Gallery (1955); Gilbert Spencer, *Stanley Spencer* (1961); M. Collis, *Stanley Spencer* (1962); George Behrend, *Stanley Spencer at Burghclere* (1965). (M. Ch.)

**SPENER, PHILIPP JAKOB** (1635–1705), German theologian and one of the leading figures in German Pietism (q.v.),

was born on Jan. 23 (new style; 13, old style), 1635, at Rappoltswiller in Upper Alsace. His father's position at the Court of Rappoltstein and the fact that his godmother was the countess Agathe von Rappoltstein brought Spener into early contact with the higher aristocracy, a relationship that proved important in the later development of Pietism. His youth was influenced by the devotional literature of English Puritanism, and his later studies at the theological faculty of Strasbourg (1651–59) determined his lifelong interest in reform of Lutheran orthodoxy. At the age of 31 he was made president of the Lutheran Church at Frankfurt am Main. There he started his *collegia pietatis*, devotional gatherings intended to encourage personal piety and private Bible study.

In 1675 Spener published his *Pia desideria* (English translation, 1964), a concentrated expression of the reform strivings that had existed for almost 100 years within Lutheranism. His reputation spread throughout Germany in consequence of this work, which contained the basic program of Pietism and was the stimulus to its promulgation in the Lutheran Church. His appointment as first court chaplain at Dresden in 1686 brought him into the most valued position in German Lutheranism. His work, however, was hindered by bitter conflict with the elector John George III, when Spener criticized the moral life of the Saxon court. The spread of Pietism aroused so vigorous an opposition from orthodox Lutherans at Leipzig University that in 1691 Spener moved to Berlin to become provost of St. Nicholas' Church. The support of the Brandenburg-Prussian Court enabled Spener to carry out many reforms, and in 1694 Halle University was founded on a Pietist basis, with Spener's disciples A. H. Francke (*q.v.*) and Christian Thomasius holding leading professorships. By the time of Spener's death in Berlin on Feb. 5, 1705, Pietism was well established. During the last years of his life Spener had retired from polemical discussions. He left over 300 writings, among which, besides *Pia desideria*, are *Das geistliche Priestertum* ("Spiritual Priesthood"; 1677) and *Die allgemeine Gottesgelehrtheit* ("General Theology"; 1680).

**BIBLIOGRAPHY.**—P. Grünberg, *P. J. Spener*, 3 vol. (1893–1906); A. Ritschl, *Geschichte des Pietismus* (1884); K. Aland, *Spener-Studien* (1943). (K. A.)

**SPENGLER, OSWALD** (1880–1936), German philosopher, was born at Blankenburg am Harz on May 29, 1880. Mathematics and natural science were the main subjects of his university education, but he wrote a thesis on Heraclitus for his doctorate, taken at Halle in 1904. Spengler earned his living as a schoolmaster until 1911, when he went to live in Munich on a small inheritance. It was about this time that he began to work on *Der Untergang des Abendlandes* (Eng. trans., *The Decline of the West*, 1926–28), of which he had completed a draft by the outbreak of World War I. The first volume of this powerful book was published in Munich in July 1918, a few months before the final collapse of the German forces. It won its author immediate acclaim from the general public, if not from professional historians and philosophers. The second volume followed in 1922, and a revised version of the first a year later. Spengler tried from 1919 onward to turn his reputation to account by assuming the role of political commentator, but he met with little success in this field. He became increasingly isolated, and his difficulties were multiplied by criticism of his work by the National Socialists, despite a certain affinity between his political ideas and theirs. (See NATIONAL SOCIALISM.) He died in Munich of a heart attack on May 8, 1936.

Spengler's reputation rests entirely on *Der Untergang des*

*Abendlandes*, which is in effect a study in the philosophy of history or in historical "morphology." Beginning, as G. Vico had done before him and as Arnold Toynbee was to do a few years later, by comparing modern Western civilization with the civilization of the Greco-Roman world, Spengler claimed to be able to discern the outline of a life cycle through which, he believed, all such civilizations must pass. Possession of this key idea, he argued, would enable us both to reconstruct the past and, more significantly, to predict "the spiritual form, duration, rhythm, meaning and product of the still unaccomplished stages of our western history." Spengler's own view of the prospects of Western civilization was a gloomy one. Since the West, he believed, had already passed through the creative stage of "culture" into the stage of reflection and material comfort (which constituted "civilization" proper in his special terminology), the future could only be a period of decline; nor was there any prospect of reversing the process, for civilizations blossomed and decayed like natural organisms, and true rejuvenation was as impossible in the one case as in the other.

Spengler's book won scant approval from professional scholars, who were scandalized by his unorthodox methods and contemptuous of his errors of fact. There could, however, be no denying his moments of genuine historical insight (as in his imaginative treatment of Greek mathematics) or the merits of his work as a contribution to social theory.

Other works by Spengler include *Preussentum und Sozialismus* (1920), *Politische Pflichten der deutschen Jugend* (1924), *Neubau des deutschen Reiches* (1924), *Der Mensch und die Technik* (1931; Eng. trans., *Man and Technique*, 1932), and *Jahre der Entscheidung* (1933; Eng. trans., *Years of Decision*, 1934). Some of his miscellaneous writings are collected in *Politische Schriften* (1932) and *Reden und Aufsätze* (1937).

**SPENSER, EDMUND** (c. 1552–1599), the author of *The Faerie Queene*, one of the great long poems in the English language, is described on his monument in Westminster Abbey, London, as "the Prince of Poets in his tyme." The original monument, which was erected by Anne, countess of Dorset, in 1620, and replaced in 1778, gave his year of birth as "1510," probably for 1550 by a calligraphic confusion then frequent. Eighteenth-century biographers conjectured that he was born in 1553, but 1552 has been preferred since G. L. Craik, in 1845, deduced it from Spenser's own reference to his age in his sonnet sequence *Amoretti* (no. 60); however, the sonnet (itself of doubtful date) is unlikely to be exact in its use of the word "fourty." According to an early tradition, he was born in East Smithfield, London. In his *Prothalamion*, besides calling London his "most kyndly Nurse," he refers to his kinsfolk the wealthy Spencers of Wormleighton, Warwickshire, and Althorpe, Northamptonshire—to three of whom, the Ladies Carey, Compton, and Strange, he had dedicated poems—as "an house of ancient fame."

Though the Scottish historian Robert Johnston (in his *Historia rerum Britannicarum*, 1655) describes him as *in tenui re natus* ("born in mean circumstances"), Spenser's education does not suggest poverty. On Feb. 6, 1569, he received a gown and a shilling from Robert Nowell's charitable bequest, with 30 other "pore schollers"; but this was a conventional label for schoolboys, and the occasion was Nowell's funeral, at which Spenser with five others represented Merchant Taylors' School. He had entered Merchant Taylors' School when it opened in 1561 under the headmastership of Richard Mulcaster, one of the most advanced educationists of the day. He left for Cambridge in April 1569; matriculated as a sizar of Pembroke Hall on May 20; and proceeded B.A. in 1573 and M.A. in 1576. In his first months at Cambridge he contributed anonymously to the apocalyptic and anti-Catholic *Theatre for Worldlings*—a translation of a prose tract by the Dutch Protestant refugee Jan Van der Noodt—22 rhymed and unrhymed translations of "Visions" by Petrarch (through Clément Marot's French version) and Du Bellay. Some of these epigrams and sonnets he revised for the later *Complaints* volume.

THE GRANGER COLLECTION  
OSWALD SPENGLER, PHOTOGRAPHED  
ABOUT 1930

In *The Faerie Queene* (Book IV, canto 11) he affectionately remembers his "mother Cambridge" and the gentle Muses and learned wits who adorned her. Among these, Gabriel Harvey (q.v.) became Spenser's "most special freende," encouraged in him a disciplined interest in the arts of language, and tried to share his enthusiasm for the modern literatures of Spain, Italy, and France. Spenser became "perfect in the Greek tongue," and, though Platonism and militant idealism were probably both deeply rooted in his nature, his sojourn in the Platonist university, and in a strongly Protestant college, helped to shape and direct these impulses.

Spenser seems to have remained at Cambridge at least until 1574-75; then there is a gap in our knowledge of his life. Nothing can now be made of the deliberately mystifying hint (in the *Shepherd's Calendar*, June gloss) of a stay in "the Northpartes," round which conjecture has played persistently. We catch an early glimpse of him in his prose dialogue *Veue of the Present State of Ireland*, where the execution of the rebel Murrough O'Brien at Limerick on July 1, 1577, is described with eyewitness detail. Edward Phillips' statement (in his *Theatrum Poetarum Anglicanorum*, 1675) that he was secretary to Sir Henry Sidney, lord deputy of Ireland, is inherently probable from his later career; and Milton (Phillips' uncle) seems to have had contacts with Spenser's family. In 1578 Spenser became secretary to John Young, who had been master of Pembroke when he was an undergraduate, and had been made bishop of Rochester early in the year; he is the beloved "Roffy" (from Roffensis, the name he took as bishop) of the September eclogue of the *Shepherd's Calendar*. Since the whole of this work was finished by April 10, 1579, it was presumably written in the bishop's "goodly Kentish garden" at Bromley, and its setting, in so far as it is not conventionally pastoral but particularized by references to Kent, is consistent with this.

The *Shepherd's Calendar*, a group of pastoral eclogues, one for each month, was entered in the Stationers' Register on Dec. 5 and published soon after under the pseudonym "Immerito." The delay in publishing it was caused by discussion with Harvey as to the best strategy for the "new poet's" first public appearance, and the elaborate critical apparatus of learned introductions and editorial glosses by "E. K." with which it was published was part of this strategy. "E. K." was perhaps Edward Kirke, a sizar at Pembroke in 1571 and probably son of a "Mystresse Kerke" mentioned in one of Spenser's letters; Edward Knight, a Puritan tract-writer of 1579, has also been suggested. Since Spenser's day readers of the *Calendar* have yielded to the temptation to speculate on the identity of "Colin Clouts" (i.e., Spenser's) cruel mistress Rosalind and to solve the anagram afforded (according to one of "E. K.'s" notes) by her name. The lady, however, is a fiction demanded both by the pastoral genre and by the poem's theme of love and greed: *caritas* and *cupiditas*; and the poem is not to be interpreted as an autobiographical allegory. However, on Oct. 27, 1579, Spenser married the 19-year-old Machabyas Chylde at St. Margaret's, Westminster, and the sestina added as an afterthought to the August eclogue and recording Rosalind's (i.e., Love's) return to Colin may refer to Spenser's bride. The names of two children of the marriage are known: Sylvanus and Catherine.

From "E. K.," and from five letters exchanged by Harvey and Spenser between Oct. 5, 1579, and April 23, 1580, and published in July 1580, we learn of a dozen works planned or finished not now extant: *Dreames* (ready for press), *Legendes*, *Courte of Cupid* (which may have become the description of the Masque of Cupid, *The Faerie Queene*, Book III, cantos 11-12; Book IV, canto 10), *Pageants*, *My Slomber*, *Dying Pellicane* (mentioned again in 1591), a translation of Moschus' *Idyll of Wandering Love*, a critical essay called *The English Poet*, and *Epithalamion Thamesis* (an experiment in English hexameters, rewritten as *The Faerie Queene*, Book IV, canto 11). The "*Nine Comœdies*" named after the nine Muses, and also referred to by Harvey, were probably never written. Harvey, in the letter referring to them, urges his friend to pursue his emulation of Ariosto with these, rather than with *The Faerie Queene* (of which he had been sent some "parcels" on April 6, 1580). His objection to the "*Elvish Queene*" was

a classical and reasonable one: antipathy to the matter of romance and fairy tale as barbarous and trivial superstition and not fit subject for a serious poem. In the same letter, he warmly welcomes the news that Spenser, with Philip Sidney and Edward Dyer (q.v.), is practising English quantitative metre, or "refourmed versifying." Spenser's interest in the art was short lived and was part of a larger concern he shared with Sidney in achieving greater rhythmical subtleties and in counterpointing the movement of English words against various metrical frameworks, of which the prosodic variety of the *Shepherd's Calendar* is a result.

With his entry into the Sidney circle early in 1579, Spenser had reached the centre of the cultural life of his time, the group that by patronage, criticism, taste, and encouragement became the chief begetter of the great flowering of Elizabethan literature. Patriotic and Puritan, its aim was to enrich England, as Italy and France had already been enriched, with a body of poetry comparable in artistry and range of forms with that of Greece and Rome—but a poetry Christian and morally serious. Spenser's first poem focused these aspirations. He became the "New Poet," "the rightest English Poet that ever I read" (according to William Webbe's *Discourse of English Poetrie*, 1586).

Politically, Sidney's uncle the earl of Leicester led the movement. By October 1579 Spenser was in his employ as a secretary and was looking forward to going to France on a mission: confusion in the printed dates of the Spenser-Harvey letters makes it uncertain whether this took place. To this period belong the lost Latin *Stemmata Dudleiana*, celebrating his patron's lineage, and, it is thought, an early version of *Mother Hubberds Tale*. In this poem the machinery of the beast fable is used (in allusion to Queen Elizabeth's own fondness for animal nicknames) to express the bitter opposition of Leicester's party to a match between the queen and the duc d'Anjou (Alençon)—a recurrent threat that had become acute since the arrival in England of the duke's agent Jehan de Simier (called by the queen her "monkey," and in Spenser's poem, the Ape) in January and the duke's own visit in August 1579, with the backing of Burghley (in *Mother Hubberds Tale*, the Fox). Sidney lost favour at court by writing a strong letter of protest. E. Greenlaw, in an article published in 1910, deduced from *Virgils Gnat* (Spenser's translation of the pseudo-Virgilian *Culex*) and the tone of its dedication to Leicester an estrangement between them, resulting from the poet's officious zeal at this time, and leading to his departure for Ireland under a cloud. This is in itself improbable, and the warm gratitude to, and respect for, Leicester (now dead) expressed in *The Teares of the Muses* make it more so. A mock-heroic poem like *Virgils Gnat* would fit only some trifling and private difference; it is a half-amusing exercise. Above all, Spenser's appointment from July 1580 as one of the two secretaries to the new lord deputy of Ireland, Leicester's friend Lord Grey de Wilton, was clearly no punishment but rather the effort of a patron himself now in disgrace and therefore with no advancement to offer, to settle his protégé. Ireland was certainly no exile to Spenser. He became deeply attached to the country and its people; landscapes, castles, place-names, poor peasantry—all became part of the imaginative life that created *The Faerie Queene*. All his writing reveals how distasteful to his quiet-loving spirit a prolonged stay at court would have been.

The rest of Spenser's life was spent in official posts in Ireland, with two visits to London to supervise the publication of poems. About 60 documents in his hand from this period prove that he journeyed with Grey throughout the country; e.g., in the actions against Baltinglas at Glenmalur in August 1580 and against the Spanish and Italian supporters of the Munster rebels at Smerwick from Oct. 5 to Nov. 10. This latter victory, in what to the Puritan Grey was a crusade against anti-Christ, became, as Artegall's defeat of Grantorto, the high point of *The Faerie Queene*, Book V.

Various leases of houses by the poet are recorded from December 1581 onward, in Wexford, Dublin, and Kildare; and on Aug. 24, 1582, he took the splendid New Abbey, County Kildare (already temporarily leased to him on July 15, 1580), near the Bog of Allen. He used it intermittently till 1590. On Aug. 31,

1582, Grey was recalled to England by a government out of sympathy with his firm repressive methods. But by then Spenser had become, in March 1581, clerk for faculties (licences and dispensations) in the Dublin court of chancery—a post he held till June 22, 1588; in 1583–84, commissioner of musters in County Kildare; and, in November 1583, or at latest by the following April, deputy to Lodowick Bryskett in the clerkship to the Council of Munster.

In this post (which he sold in 1593) he saw a great deal more of the troubled country as he traveled with the successive presidents of the council, Sir John Norreys and (1585–89) his brother Sir Thomas, and another action against the Spaniards, in Connaught and Ulster, in the winter of 1588–89. In December 1586 he is mentioned, inexplicably, as being prebendary of Effin, County Limerick. From September 1586 to October 1589 his main concern was the surveys and claims for the government's plantation of Munster. He himself was granted in September 1588 Kilcolman Castle, a forfeited estate, and neighbouring Ballingerragh. There, just south of the Ballyhoura Hills (called by Spenser in his poems, "Old Father Mole") and between his beloved Awbeg ("Mulla") and Bregog streams, he lived for the next ten years—involved periodically from October 1589 in litigation over boundaries with his Anglo-Irish neighbour Lord Roche.

Bryskett, who had Italian family connections and literary interests, kept Spenser in touch with modern poetry. Tasso's *Gerusalemme Liberata* (1581) came as fresh stimulation. To this period belongs some such incident as that recounted by Bryskett in his *Discourse of Civill Life* (published in 1606 but written before 1589) when he describes, with some literary embellishment, a meeting of friends near Dublin at which Spenser refused to talk on moral philosophy, as he had "already well entered into" a poem on this subject in "heroical verse." Bryskett may have taken a manuscript of *The Faerie Queene*, Books I–III, to London in 1587, for it apparently began to circulate in the countess of Pembroke's circle at about that time. When Sir Walter Raleigh, who owned an estate southeast of Kilcolman, visited Spenser in the summer of 1589, he heard enough of the poem to make him persuade the poet to return with him to London and interest the queen in it. The whole of this episode Spenser made into the charming poem *Colin Clouts Come Home Againe*, written when he returned to Kilcolman in December 1591 and sent with a letter to Raleigh.

The first installment of *The Faerie Queene* (Books I–III) was entered in the Stationers' Register on Dec. 1, 1589; and a letter to Raleigh "expounding [the author's] whole intention in the course of this worke" was written on Jan. 23, 1590. Two issues of the poem appeared by early April, and it was immediately successful. After a short time in Ireland in May–June, Spenser returned to London to write *Daphnida* (published in January 1591), an elegy on Douglas Howard, the wife of the poet Arthur Gorges, who died on Aug. 13, 1590, and to prepare for publication early in 1591 the nine poems new and old collected as *Complaints*. The publisher of this, William Ponsonby, explains in his prefatory address to the reader that the volume is due to the "favourable passage" his edition of *The Faerie Queene* has found among readers, and regrets that he has not recovered more of the author's dispersed works, lost during his stay overseas: notably a group of biblical and religious poems (named by Ponsonby as *Ecclesiastes*, *Canticum canticorum translated*, the seven penitential psalms, *The Howers of the Lord*, and *The Sacrifice of a Sinner*). The titles show that Spenser shared the taste for "divine poems" inspired mainly by Du Bartas' *Uranie* (1574) as translated by James VI of Scotland in 1584. The motive expressed in Ponsonby's preface may account also for C. Burbie's publication in 1592 of a translation (as by "Edw. Spenser") of the pseudo-Platonic dialogue *Axiochus* "concerning the shortnesse and vncertainty of this life, with the contrary ends of the good and wicked"—a truly Spenserian theme. The translation was probably made in 1579–80. The unique copy of Spenser's 28-page version was found in 1931 bound up with a copy of the 1679 folio edition of Spenser's *Works*. Some attribute it to Anthony Munday.

On Feb. 25, 1591, Spenser's worth as a national poet was recognized by the award of a pension of £50; this was paid regularly till his death. He himself expresses gratitude to the queen, e.g.,

in *Colin Clout* and in *Amoretti*, no. 74; but as early as 1602 a story is told by a John Manningham, in his diary, of how Burghley, always suspicious of poets, had whittled down the queen's original offer of £100. The same story appears independently in Thomas Fuller's *Worthies* (published 1662) and became a favourite with later biographers. From 1592 onward there are persistent reports that Burghley had the unsold copies of *Complaints* recalled because of the attack on him in *Mother Hubberds Tale*.

Less is known of Spenser's official work during his last seven years. He was twice justice for County Cork in 1594. On June 11 of that year (which was, at that period, Midsummer Day), he married Elizabeth Boyle and commemorated the event in *Epithalamion*, as he had recorded the courtship from late 1592 onward in the 89 *Amoretti* (or love sonnets). These were published together in 1595. His second wife was the daughter of Stephen and Joan Boyle of Bradden, Northamptonshire, and a kinswoman of the Spencers of Althorpe. They may have met through her family connection with Sir Richard Boyle, later earl of Cork. They had one son, Peregrine.

The year of Spenser's second visit to London, 1595–96, was, as to new publications, the most crowded of his career. Besides *Amoretti*, he issued in 1595 a volume containing *Colin Clouts Come Home Againe*, and a collection of verse tributes to Sidney's memory, of which the first two, *Astrophel* and the *Doleful Lay of Clorinda* (put into the mouth of the countess of Pembroke), were his own. Most important was the second installment of *The Faerie Queene*. Books IV–VI were entered in the Stationers' Register (Jan. 20, 1596), and they, with the second edition of Books I–III, must have appeared well before November 1596, when James VI of Scotland complained to the English ambassador in Edinburgh of the treatment of his mother Mary, queen of Scots, whose trial is described as the trial of Duessa, in Book V, canto 9. During this year also the *Veue of the Present State of Ireland* was written for presentation to those responsible for policy there. It was entered in the Stationers' Register on April 14, 1598, to await "further authoritee" but was first printed only in 1633 by Sir James Ware in his *Historie of Ireland: The Foure Hymnes* appeared in about September of the same year; and the *Prothalamion, or a Spousall Verse* was occasioned by the double marriage at Essex House on Nov. 8 of the earl of Worcester's eldest daughters Elizabeth and Katherine. Spenser used the opportunity to praise the earl of Essex, on whom he now placed his hopes for his country, and to pay a graceful compliment on his capture of Cádiz in August.

He returned at the end of 1596 to an Ireland increasingly shadowed by the impending rebellion of Tyrone. From its outbreak in June 1598 it rapidly spread till in October Kilcolman Castle was sacked, and the Council of Munster, with many English refugees, withdrew to Cork. Spenser had, on Sept. 30, been made sheriff of Cork on the warm recommendation of the Privy Council to the lords justices, to whom he was already known "for his good and commendable parts," his learning, and his experience in the wars. But his only remaining official duty was to carry to the Privy Council and to Cecil at Whitehall urgent letters (of Dec. 9 and 13) from Sir Thomas Norreys on the desperate state of affairs. To these he added three memoranda of his own, preserved in the Public Record Office as "A breife note of Ireland," and including a report addressed to the queen, "Out of the ashes of disolacon and wastnes of this your wretched Realme of Ireland." He arrived in London on Sunday, Dec. 24, and on Dec. 30 Cecil paid him £8 for his mission. On Saturday, Jan. 13, 1599, he died in Westminster, in King Street, according to Ben Jonson. He was buried at Essex' expense in Westminster Abbey close to Chaucer, and William Camden (writing in 1615) relates that many poets threw into his open grave their elegies and the pens that wrote them. An attempt in 1938 to recover these relics was foiled by ignorance of the position of the grave, the monument having been moved.

The story that Spenser died "for lack of bread" (as Ben Jonson told William Drummond of Hawthornden, in 1618) is, in view of his official status and patrons, incredible. There is no hint of it in John Chamberlain's letter reporting the death of "our principal

poet" four days after the event; it is first suggested in Joseph Hall's lines to Camden in 1600, and in the Cambridge play *The Returne from Parnassus*, part 2 (late 1601). Thus early began the romanticizing of "mild Spenser, called from Faeryland/To struggle through dark ways." This phrase of Wordsworth's enshrines a deeply misleading antithesis between the poem and the poet's life, since an active and strenuous career was indispensable to the writing of *The Faerie Queene*. More important is the tradition, recorded as early as 1607, that manuscripts of later parts of *The Faerie Queene* were lost in the destruction of Kilcolman. The first folio edition (1609) of the whole of *The Faerie Queene* prints, as well as the six completed books, two cantos, plus two stanzas of *Mutabilitie* from a seventh book, a "Legend of Constancie." Intensive search in Ireland and England in the mid-17th century unearthed no more of what Spenser must have written during the last 4½ years of his life.

### THE WORKS

**Pastorals.**—Since Spenser's work is conceived in terms of the 16th-century aesthetic theory of the literary "kinds," each with its own decorum of style and conventions, understanding of it begins with recognition of the genres he felt himself to be making. "E. K." is at pains to underline in his introduction to the *Shepherd's Calendar* that the new poet is beginning, like Virgil, with pastorals, and the "October" eclogue looks forward to the epic he will write in the future just as the Proem of Book I of *The Faerie Queene* looks back to the "lowly Shepherds weeds." But *The Shepherd's Calendar*, unlike earlier pastorals by Mantuan, Sannazaro, and Spenser's favourite, Clément Marot, is a single poem, not a haphazard series of 12 eclogues. Its unifying "calendar" framework was suggested by the popular French devotional manual *Le Compost et Calendrier des Bergiers*, which was well known in translation. Spenser's translation of the whole pagan pastoral world into Christian terms is signaled by his opening the year in January instead of in March, so counterpointing (as the General Argument to the poem explains) nature's winter death against the birth of the Redeemer, who renews "the state of the decayed world." The poem opposes the good shepherd, the "shepherd great, that bought his flocks so deare" (i.e., Christ), to various bad and mercenary shepherds. Akin to the *cupiditas* (greed) of the hirelings is the crippling love of the shepherd Colin Clout for the faithless Rosalind, which has brought his flock to wretchedness, makes him break his pipes in despair, and turns him from the *caritas* (loving-kindness) of Hobbinol's (Harvey's) friendship. The theme of the two loves, to be developed so fruitfully in *The Faerie Queene*, is already shaping in Spenser's imagination. "April" offers, in the song to Eliza (Elizabeth I), an exquisite example of the poetry that Colin was once capable of; and the bleak end he faces in "December" is heightened by the death of Dido so nobly mourned and robbed of its sting in "November"—*La mort ny mord* ("Death bites not there") since "one that dyed for al."

Attention has been distracted from the poetic greatness of *The Shepherd's Calendar* by its many other importances: its inauguration of English pastoral (see PASTORAL); its program for embellishing English, as the Pléiade poets in practice and precept had embellished French, by recovering ancient and dialect words (a motive that guided Spenser to the end), and by judicious coinages and borrowings; the rhetorical and syntactical art so admired by "E. K." in the glosses; the variety of forms—fable, satire, complaint, paean, dirge, sestina, roundelay; and the references to contemporaries, of which only a few are certain and none to be rigorously pressed.

The pastoral machinery that in *The Shepherd's Calendar* marvelously holds together the roles of God-inspired poet-priest-ruler, so achieving the timelessness claimed by the "December" gloss, is transposed in *Colin Clouts Come Home Againe* into charming autobiographical anecdote: the visit with the Shepherd of the Ocean (Raleigh) to Cynthia's court, and the ladies and poets there. There is the traditional praise of country life as against courtly corruption; the Hobbinol and Rosalind themes are resumed in a happier key. The pastoral elegy *Astrophel* fittingly

laments Sidney as himself a pastoral poet—author of *Arcadia* and *Astrophel and Stella*. *Daphnaïda* inserts into a pastoral framework an allegorical lyric modeled on the grief of the Knight in Black in Chaucer's *Book of the Duchess*. Its obvious derivative-ness, highly patterned rhetoric, and sevenfold repetitions dramatize the stubbornness of Alcyon's refusal to be comforted (Alcyon being the pastoral name given to Arthur Gorges, Douglas Howard's husband), over against moments of intensely realized love and loss.

**Complaints.**—The title suggests the medieval marriage of elegiac and satiric tones. Of these "sundrie small Poemes of the Worlds Vanitie," *Mutopotmos, or the Fate of the Butterflie*, the only one entirely new in 1591, is the finest. The butterfly Clarion, destroyed by the spider Aragnoll, is in fact the victim of the ancient "dolorous debate" between Pallas and Arachne, which Spenser characteristically interweaves with his own version of the jealousy of Venus against Astery and Psyche. The whole, an impeccably tactful re-creation of the myth of "the drierie stownd . . . That of all happines hath vs deprived," of Satanic evil, temptation, and fall, is Spenser's miniature epic in answer to the mock epic *Culex*, which he had rendered as *Virgils Gnat*. So also to his versions of Petrarch's *Visions* and Du Bellay's *Songe* and *Antiquitez de Rome* (*Ruines of Rome*) he added his own specimens in the same kind: *Visions of the Worlds Vanitie*, and the vision pageants that close *The Ruines of Time*—an elegy on Leicester, Sidney, and Walsingham that turns the popular medieval theme of "Falls of Great Men" into a lament for the world's lost glories and a claim that only the immortality conferred by poetry survives the universal vicissitude. This last is the subject of *The Teares of the Muses* (the title taken from a Latin poem by Harvey), the clarification of a genre that can be seen emerging in earlier 16th-century complaints of the neglect of the arts by a barbarous age. Theseus, in Shakespeare's *A Midsummer Night's Dream* (Act V, scene i, li. 54), dismisses this poem as "some satire, keen and critical." But the only purely satirical poem by Spenser is *Prosopopoia, or Mother Hubberds Tale*. Though formally this is in the great late medieval tradition of *Reynard the Fox* (q.v.), the resources of animal symbolism are little exploited, and the style and method—attack on the several estates of the realm—align the poem with William Langland's *Piers Plowman* and the work of John Skelton and Sir David Lyndsay (qq.v.), and with contemporary prose tracts on the ills and abuses stemming from the immense social and economic changes of the time.

**Sonnets; Spousals; Hymnes.**—Except in the three Petrarch and Du Bellay "Complaints," Spenser preferred the sonnet with linked quatrains developed from native metres by the poets of the Scottish court (see SONNET). Two sonnets to Harvey and Leicester (c. 1586) are in this form. The *Amoretti*, like other sonnet sequences of the time, have a narrative basis, hinted by the passing seasons (New Year, Easter) and the vicissitudes of the poet's love. But this courtship is, uniquely, crowned with marriage. The time-worn conceits of courtly wooing heighten the paradox of the Christian consummation celebrated in *Epithalamion*. This last, the most perfect of Spenser's poems, is a manifold symbol of fulfillment based (in 24 stanzas) on the circle of day and night, reinforced with myth and biblical echo and the movement from pains and death to joys, birth, and immortality with the saints, and dramatizing in its images of time the victory over time that its last line prays the poem itself will be. These images also mark the three great phases of the day centred in the marriage service. The marriage ode of Catullus and the French Pléiade poets has here been radically remade.

*Prothalamion* is, as its refrain says, a betrothal song, a rare genre for which Spenser invented the title. The joyous occasion is framed by the medieval device of the allegorical swan procession watched by the traditional world-weary poet, and hopes for the young couples merge with hopes for England (whose annual "Brydale day"—Nov. 17, Accession Day—is at hand: stanza 9) and a rebirth in the earl of Essex of the fallen nobility Spenser has personal reason to mourn in the fall of the earl of Leicester.

Spenser's pretended "retraction" of the first two of his *Powre Hymnes* of love and beauty, composed "in the greener times of my youth," is no doubt only a device for pointing the contrast between

the halves of his diptych, the "natural" and the "celestial," figuring under Platonic colouring stages like those in medieval Christian devotion. The last two hymns celebrate divine creativity, and Sapience (Old Testament "Wisdom," identified with the Word) enthroned with God.

**A Veue of the Present State of Ireland.**—If the modern reader can restrain his anachronistic horror at the ruthlessly repressive policy advocated for Ireland, he may watch unfolding in firm dramatic prose a mind equipped by firsthand observation; furious at injustices, abuses, and double-dealing; informed in political and historical theory, *e.g.*, of Jean Bodin (*q.v.*); and with a firm grasp of the civil and military needs in that "sweete countrie."

**The Faerie Queene.**—The debate of the 18th-century commentators on Spenser about the epic status of *The Faerie Queene* may be resolved if (with E. M. W. Tillyard) we define epic as the embodiment in a fiction of the whole ethos and ideals of a "heroic age." Spenser was himself inspired by the critical battle fought over the Italian romances from 1548 onward, and reaching a compromise in the 1580s in the theory and practice of Torquato Tasso (*q.v.*): romantic variety in epic unity, the Christian supernatural as the "epic marvellous," war and love as the matter. His letter to Raleigh affirms his position by citing Homer and Virgil along with Ariosto and Tasso as models, by insisting on the overall unity the poem completed is to have, and by pointing to his use of the epic device of thrusting into the heart of the narrative in Book I. That the annual Feast of Gloriana, the source of the 12 tasks that are the poem's action, is to be presented last (so that in fact it was never written) sets up that sense of striving toward a goal, of outgoing and return, so central to the world of the poem; and the goal is kept before us in Arthur's dream-inspired search for Gloriana through the world. This framework is Spenser's invention, based on visions of fairy mistresses in the much read *Arthur of Little Britain* and Chaucer's *Sir Thopas*, and on the Accession Day festivities.

The poem as we have it (which consists of only 6 books and a fragment of the seventh, instead of the 12 intended) ends with the poet's own prayer for sight of a farther goal, the sabbath of the God of Sabaoth. But formally the poem owes its whole being to the Italian *romanzi*, as the Italianate names of its characters acknowledge. From them comes the inventive energy of *entrelacement*—continually bifurcating and infolded narrative; from Boiardo come the book and canto division (the first English use of the "canto"), the verse argument of each canto, the moralized opening and promissory ending of cantos; from Trissino, the name Acrasia and hints for Duessa; from Tasso, with little change, such episodes as the Idle Lake and the Bower of Bliss—for Tasso is closest to Spenser in gravity of spirit. The debt to Ariosto in story and motif is by far the greatest.

Spenser "overgoes" his models (as he hoped) simply by taking seriously the capacities of the romance form, by exploiting romance as a paradigm of human experience: the moral life as quest, pilgrimage, aspiration, as eternal war with an Enemy still to be known, as encounter, crisis, the moment of illumination—ethics with the dimensions of mystery, terror, love, and victory added, and all the generous virtues exalted. As setting Spenser invents the "antique image" of Faerie, a land of true fame; its capital Cleopolis, city of repute; its queen Glory, which for the Platonists was a third region besides Nature and Grace. His general aim is to change the reader, "to fashion a gentleman or noble person

in vertuous and gentle discipline" (as he says in his letter to Raleigh)—the shaping aim of art, perfecting nature. His method is the "continued Allegory or darke conceit," polysemous like Dante's. The mode of its operation is clearly established in Book I: (a) Every chivalric romance (as G. K. Chesterton observed) has three characters, dragon, maiden (Una), and knight (Red Cross); to these add wicked magician (Archimago), witch and siren (Duessa doubling these roles), and dwarf; "Salvage Man"; estrangement and reunion, and rescue from danger by the bravest knight in the world (Arthur); and marriage. (b) The Red Cross knight's temptations and mistakes are Everyman's instruction as he journeys through life. (c) His device, "a bloudie Crosse. . . The deare remembrance of his dying Lord," and the introductory letter's reference to the armour of the Christian warrior firmly place the dragon who keeps the parents of Una (who personifies Truth) out of their kingdom of Eden and who is vanquished in a three-day combat; add the rich imagery from the book of Revelation (commended to Spenser by Harvey as a poetic model in 1580), the Christian ethics taught in the House of Holiness, and the divine gracelike function of Prince Arthur. (d) The hero is the patron saint of England (Book I, canto 10, stanza 61), and the traditional pageantry of the cult of St. George is the source of Una's lamb, her arming of the Red Cross knight, and his twice-repeated revival during the fight. Arthur, the "Briton Knight," chief of the Nine Worthies, focuses this aspect of the poem, recalling the 16th-century myth of his reincarnation in the Tudor dynasty and the yearly impersonation in London of his company of knights. Modern impatience with the patriotic topicalities, ecclesiastical and political, throughout the poem, including its inspiration by the queen as by a muse, is a failure to recognize the apocalyptic light in which Spenser's countrymen saw the great conflict of their time between Protestant England and Catholic Spain. To him, as later to Milton, the war of Good and Evil was here and now.

Between the mid-17th century and Edward Dowden's 1882 essay (in *Transcripts and Studies*, 1888), the sage and serious poet whom Ben Jonson (like all his contemporaries) would have "read for his matter" was little regarded, and *The Faerie Queene*, his most important work, was misunderstood. Hazlitt assured the reader that if he doesn't meddle with the allegory the whole is as plain as a pickstaff. Lamb, however, sanest of Spenserian critics, saw that in the inner laws of Fairyland "we are at home and upon acquainted ground." Misunderstanding of the titles of the books is partly to blame for the chill some readers feel. Book I, called "Holiness," in fact tells the fable of sanctification and reenacts man's Fall and Redemption; Book II—Temperance—is the defense (under the guidance of a Palmer) of God's highest handiwork, man's body, which he hath tempered together like an artist and of which the harmonious architecture of the House of Alma is a gracious metaphor and the tinsel of the Bower of Bliss a travesty; the Legends of Chastity and Friendship (Books III and IV, the poem's core) are a single intricate exploration of love, lawful in Britomart, sterile and terrifying in Busirane's House, and fulfilled in the great images of Concord in Book IV, cantos 10–12—the Temple of Venus and the marriages of Thames and Medway and Florimel and Marinell; Concord, or hierarchy, is the basis of the Book of Justice (Book V); and Calidore's vision (Book VI, canto 10) of the Graces dancing to Colin's piping bodies forth that Heavenly Harmony of which Courtesy or "civilitie" (humble reverence for our diverse relations with others) is the earthly type. In the final fragment—the "mutability" cantos of Book VII, *The Legend of Constancy*—the Venuslike Christlike figure of Nature triumphs over change and decay by showing them to be part of the world's stability—"eterne in Mutabilitie."

Spenser deserves the often misunderstood title of "poet's poet" by being master of an art perfectly adapted and directed to its end: picture, music, metre, story, all indefeasibly one with their *significacio*, a moral heraldry of colours, emblems, legends, folklore, mythical allusion, all evoking deep instinctive responses. To enjoy the sensuous surface, to spell it out aright, is at once to take the "message," or rather, not to accept a doctrine but to undergo an experience, an ascent in vision with the protagonists. The

allegory is untranslatable. It is significant that the "Aristotelian" scheme of the "xii. private morall vertues" that the poem's 12 books were intended to expound (the epic number, by happy chance) lay ready to Spenser's hand in the many derivatives from Aquinas that dealt with princely and knightly instruction; and, on the other hand, the landmarks of his poem—castle, great house, forest, fountain, lake, hill—had been drenched in meaning by their use in pageant and interlude. Even the stanza he created aligns the poem with a long tradition; it is the finest of many 15th–17th century variants of Chaucer's "meetre heroically," as George Puttenham called rime royal in 1589, by far the commonest measure between Chaucer and Sir Thomas Wyatt, and used by Spenser himself in the *Ruines of Time* and the *Powre Hymnes*.

To his contemporaries Spenser was "our only living Homer," "the Virgil of England," "our second Chaucer." He is in truth the English Dante.

**BIBLIOGRAPHY.**—*Editions:* The Variorum edition of the Works, ed. by E. Greenlaw *et al.*, 9 vol. (1932–49; Index 1957) contains a summary of Spenserian scholarship and criticism. Other editions include the *Poetical Works*, ed. by J. C. Smith and E. de Selincourt, 3 vol. with textual notes (1909–10; 1 vol., with abridged notes, the Spenser-Harvey letters, and introduction, 1912); the *Works*, ed. by W. L. Renwick, 4 vol. (1928–34), omitting the *Faerie Queene* but including the *View of the State of Ireland*; the Cambridge edition, by R. E. N. Dodge (1908); and the Globe edition, by R. Morris and J. W. Hales (1869), which includes the *View*. . .

*Spenserian Studies:* A. C. Judson, *The Life of Spenser* (1945), is included in the Variorum edition. Aids to Spenser studies include C. G. Osgood, *A Concordance to the Poems of Spenser* (1915); C. H. Whitman, *A Subject Index to the Poems of Edmund Spenser* (1918); F. I. Carpenter, *A Reference Guide to Edmund Spenser* (1923), supplement by D. F. Atkinson (1937); F. R. **SPENSERIAN STANZA**, a verse form so called from its invention by Edmund Spenser for his *Faerie Queene* (1590–1609). Its origin is disputed; Jakob Schipper derives it from the Old French ballade (*q.v.*), others from the Italian ottava rima (*q.v.*). Probably, however, its origin is Chaucer's eight-line *Monk's Tale* stanza, to which Spenser added a ninth line with an extra foot (alexandrine), thus making eight iambic pentameter lines and a ninth of six iambic feet. The rhyme scheme is *ababbcc*. Spenser's sonnet scheme is similar (see *SONNET*).

The Spenserian stanza was seldom used in the 17th century though Giles and Phineas Fletcher made adaptations of it. In the 18th century it was revived by Mark Akenside in "The Virtuoso," William Shenstone in "The Schoolmistress," James Thomson in *The Castle of Indolence*, James Beattie in *The Minstrel*, and Burns in "The Cotter's Saturday Night." In the 19th century the Spenserian stanza was revived again by English poets of the Romantic movement—Byron in *Childe Harold's Pilgrimage*, Keats in "The Eve of St. Agnes," Shelley in *Adonais* and "The Revolt of Islam"—and by Tennyson in "The Lotus-Eaters." Oliver Wendell Holmes aptly described the Spenserian stanza in these verses:

The sweet Spenserian, gathering as it flows,  
Sweeps gently onward to its dying close,  
Where waves on waves in long succession pour,  
Till the ninth billow melts along the shore; . . .

(G. W. A.)

**SPERANSKI, MIKHAIL MIKHAILOVICH**, COUNT (1772–1839), Russian statesman who renovated the structure of administration under the emperor Alexander I, was born at Cherkutino in the Vladimir region on Jan. 12 (new style; Jan. 1, old style), 1772, the son of the village priest. After rising to be professor of mathematics and physics in the ecclesiastical seminary in St. Petersburg, he entered the government service in 1797 and quickly attracted the attention of the tsarevitch Alexander. When the latter had become emperor as Alexander I (*q.v.*), Speranski was appointed secretary of state (1801) and put to work in the ministry of the interior, where he remained until 1807. In 1808 he accompanied Alexander to Erfurt for the conference with Napoleon, who described him as "the only clear head in Russia."

From 1809 to 1812 Speranski was all-powerful in Russia; he replaced the earlier favourites at court and was practically sole minister. Intelligent, honest, hardworking and blessed with a lucid style of writing, he started many projects (including one of a constitution, 1809) and gave concrete administrative shape to Alexander's early visionary ideals. Speranski's strength lay in his mastery of bureaucratic operation, in his genius for organization and administration. He streamlined procedure and clarified objectives already adopted; he put final touches on the organization of the ministries, the council of state and the Siberian administration. Yet at the same time he gave a direction to planning and furthering the development of a systematic national policy. Liberal in that he desired spiritual, moral and economic progress, Speranski willingly supported enlightened bureaucratic absolutism as the means of effecting the necessary reforms. An introvert who bridled the expression of his own opinions, he was thwarted in many of his projects as Alexander's liberalism faded.

Speranski's absorption in work and his social isolation left him exposed to the intrigues of enemies at court. On the eve of Napoleon's invasion of Russia, the grand duchess Catherine, N. M. Karamzin, F. V. Rostopchin and G. M. Armfelt involved him in a charge of treason. Although Alexander did not credit the charge, he had begun to fear that Speranski's realization of some of the measures that he himself had conceived might undermine his autocratic authority, and on March 29 (N.S.; 17, O.S.), 1812, he dismissed Speranski and exiled him (first to Nizhni Novgorod, then to Perm). In 1816, however, Speranski was reinstated in the public service as governor of Penza, and in 1819 he was appointed governor general of Siberia, for which he drew up a new scheme of government. In 1821 he was recalled to St. Petersburg and entered the council of state. The major productions of his last years were the complete *Collection of the Laws of the Russian Empire*, 45 vol. (1830), and the systematically co-ordinated *Digest of Laws*, 15 vol. (1832–39). Created count by the emperor Nicholas I in Jan. 1839, Speranski died a few weeks later, on Feb. 23 (N.S.; 11, O.S.), in St. Petersburg.

See Marc Raef, *Michael Speransky, Statesman of Imperial Russia, 1772–1839* (1957) and *Siberia and the Reforms of 1822* (1956). (G. A. LN.)

**SPERMATOPHYTES (SPERMOPHYTES)**, the name often used in botany to denote the seed plants, including the true flowering plants or angiosperms (*q.v.*) and the conifers and their allies or gymnosperms (*q.v.*).

**SPERRY, ELMER AMBROSE** (1860–1930), U.S. inventor, whose gyroscopic compasses and stabilizers greatly contributed to the safety and comfort of sea and air navigation, was born at Cortland, N.Y., on Oct. 12, 1860, and studied at Cornell University, Ithaca, N.Y. He began early to experiment with electric arc lights and in 1880 established a factory in Chicago to manufacture an improved model that was highly successful. He then invented the electric rotary and chain undercutting mining machines and other mining apparatus and established another factory to manufacture this machinery. He next designed an electric industrial locomotive and motor transmission machinery for streetcars. After 1900 he established a research laboratory in electrochemistry at Washington, D.C., where he invented the chlorine detinning process and a process for producing white lead from impure lead. In 1915 he produced his high-intensity arc searchlight.

Chief of Sperry's inventions related to the gyroscope (*q.v.*) is

the gyrocompass (*q.v.*), first installed on the battleship "Delaware" in 1911. This compass, unaffected by iron and steel, entirely superseded the magnetic compass on submarines and battleships and was placed likewise on merchant ships. Sperry also designed and manufactured electrically sustained gyros for torpedoes. During World War I he developed aerial torpedoes with automatic gyrocontrol which proved effective at a range of 35 mi. Further experiments yielded the gyropilot for the steering of ships, the automatic gyropilot for stabilizing airplanes, the gyroscopic roll and pitch recorder for the testing of ships, and, finally, a gyroscopic ship stabilizer that was installed on a number of ships in the U.S., British, Italian, and Japanese navies. Sperry died at Brooklyn, June 16, 1930.

See "The Engineering and Scientific Achievements of Elmer A. Sperry," *Mech. Engng., N.Y.*, vol. xlix (1927). (S. C. Hr.)

**SPEUSIPPUS** (d. 339/338 B.C.), the successor of Plato as head of the Greek Academy (see **ACADEMY, GREEK**), was a nephew of Plato and had played a great part in his uncle's relations with Dionysius II of Syracuse and with Dion (see **PLATO**). An extant letter from Speusippus to Philip of Macedon, in which he violently attacks Isocrates (his rival for Philip's favour), is further evidence of his political interests.

Of Speusippus' philosophical writings very little more than the titles survives, so that for knowledge of his doctrines we have to rely on reports and scanty fragments, the longest being from a work *On Pythagorean Numbers* (explaining such matters as the "perfections" of the number ten). He followed the lines of what Aristotle presented as Plato's doctrines; viz., the timeless derivation of all reality, intelligible and sensible, from two opposite principles, often called "the One" and "the indeterminate dyad" (the modern terms "constant" and "variable" perhaps convey somewhat similar notions), which were assumed to explain the presence of both unity and multiplicity in the universe. To this doctrine Speusippus gave a peculiar turn. Whereas other Academics assumed that "the One" and "the dyad" would also be principles of good and evil respectively and be so by being themselves good and evil, Speusippus denied that "the One" was good or "the dyad" evil; in the same context he also denied the identification of "the One" with the divine mind. Specifically, good and even being itself would appear only in the later stages of the derivative process mentioned above, so that "the One" would be no more than the germ of the good and of being and thus less than either. Such a doctrine would make Speusippus a kind of evolutionist (with the good as an end product). Yet the reports of Aristotle on which such an interpretation is based are perhaps ambiguous and misleading. There is indeed some evidence that what Speusippus meant was that "the One" is non-being in the same sense in which the Plotinian "One" is non-being; viz., by being the source of all being and thus superior to it. Another aspect of the same doctrine is the derivation of successive spheres of reality—with numbers (which exist independently from sensibles and which in Speusippus' doctrine take the place of Plato's ideas) and geometrical magnitudes as the first sphere or spheres and with sensibles as the last. "The One" and "the dyad" appear in each sphere in an appropriately different form, which Aristotle criticized as making the spheres mutually independent, so that Speusippus' universe looks like an incoherent tragedy consisting of episodes and lacking dramatic unity. According to Aristotle, between the spheres of mathematical and of the sensible (body) Speusippus inserted the sphere of the soul. Iamblichus, however, reports that Speusippus defined the (world?) soul as the idea (in the sense of "form") of what extends in all dimensions, which makes the soul a mathematical entity (geometrical form). In any case Speusippus in some way seems to have intimately connected the soul with mathematical—as did Plato in the *Timaeus* and Xenocrates in defining the soul as self-changing number. As to individual souls, Speusippus asserted the immortality of the whole soul, not only of its reasonable parts.

On the whole, Aristotle is highly critical of Speusippus. Nevertheless, Speusippus' *Similitudes*, a kind of comparative anatomy or physiology of plants and animals, are comparable to Aristotle's *History of Animals*. Whether the *Similitudes* were ultimately

empirical or logico-ontological is dubious; if the latter interpretation is the right one, the *Similitudes*, together with his classification of names into synonyms, homonyms, etc., may somehow have been connected with Speusippus' doctrine that no single thing can be defined unless all have been, since classification and definition are closely related.

In introducing the concept of "knowledge-like sensation," a concept related to problems in Plato's *Theaetetus*, Speusippus perhaps tried to soften the strict ontologico-epistemological dualism of Plato. (See **KNOWLEDGE, THEORY OF: Plato**.) Many scholars see in Speusippus the representative of strict antihedonism, discussed in Plato's *Philebus*. His definition of happiness as the perfection of one's natural condition tends to derive the norm of conduct from nature.

**SPEY**, a river in Scotland, flows for 107 mi. (172 km.) in a mostly straight course northeast across the Highlands, north of the Grampians, and enters the Moray Firth between Buckie and Lossiemouth. It rises at about 1,150 ft. (350 m.) in the Corrieyairack Forest, 1 mi. W of the small Loch Spey and a few hundred yards from the west-flowing Roy-Spean-Lochy drainage. It is reputed to be one of the most rapid rivers in Scotland and is well known for salmon fishing. It flows mainly through an upland corridor between highland blocks, taking tributaries from the Monadhliath Hills, the Grampians, and the Cairngorms and draining much of southeast Inverness County, east Moray, and central and southern Banff County. The river swings between great sweeps of terraces it has cut among the hummocky glacial deposits, amid which are small lakes (Lochs Insh, Alvie, Garten, etc.) or drained lakes. The shingle spit across the shifting river mouth has been cut four times within a hundred years, and plans to make a fifth cut were approved in 1961. There are residues of the Scots pine-juniper forests; e.g., in Rothiemurchus. Strathspey, the lower valley, was the home county of the Grants, with their slogan of "Stand fast Craigellachie" (a defensible hill bordering their part of the strath). (A. T. A. L.)

**SPEYER** (SPIRES), a town of West Germany in the *Land* (state) of Rhineland-Palatinate, Federal Republic of Germany, on the left bank of the Rhine, 16 mi. (26 km.) S of Ludwigshafen. Pop. (1961) 38,485. Remains include the Altpörtel (old gate) with a late Romanesque gate tower (13th century); the Jews' Bath with subterranean vaulting (c. 1100); parts of the 13th-century town walls; and the 18th-century Baroque Church of the Trinity. The Palatinate historical museum houses a unique wine museum. The Romanesque cathedral was founded in 1030 by the emperor Conrad II. Notable are the crypt and the imperial vault where eight German emperors and kings, three empresses, and a princess lie buried. The cathedral was gutted in 1689 and reconstructed from 1772 to 1784. It was again restored after World War II and reconsecrated in 1961.

The medieval city is surrounded by new industrial and residential areas. There is a college of administrative studies, the only one of its kind in the Federal Republic. A modern open-air swimming pool lies on the Rhine. Speyer is at the junction of the roads from Bonn to Karlsruhe and from Kaiserslautern to Heidelberg. The rebuilding (1956) of the Rhine bridge, destroyed in 1945, restored an important route across the Rhine. There is an electro-technical industry, an oil refinery, metal and wood processing, printing, cotton spinning, and chemical and shoe manufactures. There are also stone, glass, and brick works, breweries, sparkling wine (*sekt*) cellars, and aircraft factories.

In 400 B.C. Speyer, known as Noviomagus, was the main Celtic

settlement in the Palatinate. Under the Romans a castle was built on this site and a flourishing trading town grew up, only to be destroyed during the barbarian invasions. In the 13th century Speyer became a free imperial city, and 50 imperial diets were held there. The town was destroyed by French troops (1689) in the War of the Grand Alliance. In 1797 Speyer was incorporated into the French Republic. From 1816 to 1945 it was the capital of the Bavarian Palatinate. (Fz. S.; G. Gr.)

**SPEZIA, LA**, a city and seaport of Liguria, Italy, and headquarters of La Spezia Province, lies 70 mi. (113 km.) SE of Genoa (Genova) by road. Pop. (1961) 121,893 (commune). It is one of Italy's major naval bases and stands at the head of a gulf that provides good protection for ships. Most of the town's industries are connected with the sea; the shipbuilding yards are among the most important in Italy, and there are foundries and refineries. The naval arsenal was destroyed during World War II and has been rebuilt. Near it is a naval museum. Much of the city is modern, and there is a public park. The archaeological museum has a collection of menhirs cut in the form of human figures, and Roman remains from the ancient city of Luna. La Spezia is on the main railway and road from Genoa to Rome.

La Spezia was inhabited in Roman times, but little is known of its history before 1276, when it was sold to Genoa by the Fieschi. It became a maritime prefecture in the French Empire and then part of the Duchy of Genoa in the kingdom of Sardinia. After the transfer of the military fleet from Genoa in 1857, it became a naval headquarters.

**LA SPEZIA PROVINCE** (area 341 sq.mi. [882 sq.km.]; pop. [1961] 237,808), formed in 1923, centres on the valley of the Vara River, which is surrounded by mountains of the Ligurian Apennines (Mt. Gottero, 5,380 ft. [1,640 m.]), and borders the provinces of Parma (north) and Massa-Carrara (east). The towns of Portovenere and Lerici, famous for their association with Byron and Shelley, stand on opposite sides of the Gulf of La Spezia, and the coast has holiday resorts. There is much forest; cultivation is mainly along the lower Magra River; and there is fishing. (C. Tr.)

**SPHALERITE** (BLENDE or ZINCBLENDE), a sulfide of zinc, is the chief ore of that metal. (For production and uses see ZINC.) Sphalerite, the commonest zinc mineral, and galena, the most abundant ore of lead, are intimately associated in most of the important deposits of these metals. The name derives from a Greek word for "treacherous," in allusion to the ease with which the dark-coloured, opaque varieties are mistaken for galena. The synonyms blende and zinblende, from the German word for "blind," similarly allude to the fact that it does not yield lead. Associates, in addition to galena, include chalcopryite and pyrite among metallic minerals, and quartz, barite, dolomite, calcite and siderite as gangue minerals.

In the United States the most important deposits of sphalerite are found in the Mississippi valley region. There it occurs chiefly with chalcopryite, galena, marcasite and dolomite in solution cavities and brecciated zones in limestone and chert. Similar deposits occur elsewhere—in the region of Silesia in Poland, the Moresnet district in Belgium and north Africa. Sphalerite also has world-wide distribution as an ore mineral in hydrothermal vein deposits, in contact metamorphic zones and in high-temperature replacement deposits. Crystals of outstanding beauty and perfection are found in cavities in a dolomite rock in the Binnenthal, Switz., and a transparent variety of a golden colour occurs at Picos de Europa, Santander, Spain. Fine specimens also come from Cornwall, Derbyshire and Cumberland in England, and from Bottino in Tuscany, Italy.

The crystal structure of sphalerite is based on a tetrahedral, four-co-ordinated framework of zinc and sulfur atoms in which the bonding is essentially covalent. The structure is similar to that of diamond, and may be imagined as derived therefrom by the alternate substitution of zinc and sulfur atoms for carbon. The unit cell dimension is 3.40 Å. The common crystal forms are the tetrahedron and the dodecahedron. The crystals frequently occur as simple or multiple contact twins, or as complicated lamellar intergrowths, in which the twin axis is [111]. Sphalerite ordinarily occurs in massive granular form, less commonly as fibrous

aggregates with a layered structure or as dense microcrystalline masses. It has a well-developed dodecahedral cleavage, and the fracture is conchoidal. The hardness is 3.5 to 4, and the specific gravity of pure material is 4.0. The colour varies widely. Generally it is a shade of brown, but some sphalerite is green, yellow or, in crystals of high purity, almost colourless. Material containing iron is brownish-black or black. Sphalerite may fluoresce when irradiated with ultraviolet light or X-rays, and some specimens emit light when scratched with a sharp point (triboluminescence). According to the formula, ZnS, sphalerite contains 67.1% Zn and 32.9% S. Usually, however, it contains iron in solid solution up to a limit of about 26%, and both manganese and cadmium may be present in small amounts. (Cl. F.)

**SPHENE** (TITANITE) is a titanium-bearing mineral consisting of calcium titanate. Sphene crystals vary considerably in habit, but are generally thin and wedge shaped; hence the name, from a Greek word for "a wedge." The colour is green, yellow, brown or black, and the lustre resinous to adamantine. Crystals, which are monoclinic, are transparent to opaque. The composition is  $\text{CaTiSiO}_6$ ; hardness is 5.5; specific gravity 3.5. Sphene is cut as a gem stone, though it is too soft to stand much wear; because of its high dispersive power it gives brilliant flashes of prismatic colours. As small crystals, it is found in igneous rocks (granite, syenite, trachyte, phonolite, etc.) and in gneiss, schist, crystalline limestone and pegmatite.

**SPHENOPSIDA**, a class (or subphylum) of early spore-bearing vascular plants whose sole living genus, *Equisetum*, composes the horsetails. The group flourished as trees, e.g., *Calamites* species, during the Carboniferous Period but appeared as early as the Lower Devonian. In its fossil history it is believed to have constituted a larger portion of the flora of the earth than at the present time. Other fossil genera were possibly shrublike (*Calamophyton*) or vinelike (*Sphenophyllum*).

Horsetails are worldwide in distribution except for certain parts of Australia. The majority of the 30 living species occur in the Northern Hemisphere and are generally found in wet or damp habitats, although some species have become adapted to drier conditions. Some botanists recognize six different orders in the class; others restrict the class to four orders. There is only one order, Equisetales, that has both living and extinct species; all others comprise extinct sphenopsids. Sphenopsids, fossil and living, characteristically have whorled leaves and conspicuously jointed stems. In certain orders the stems show longitudinal ribs. When branches do occur, they develop in alternating radii with the leaves. This arrangement is known in no other group of living plants, for elsewhere buds usually arise in the axils of leaves.

The horsetails, like other vascular plants, have an alternation

(ABOVE) FROM A. CRONQUIST, "INTRODUCTORY BOTANY"; HARPER & BROS.; (RIGHT) ROCHE

A COMMON HORSETAIL (*EQUISETUM ARVENSE*) WITH CONE-SHAPED REPRODUCTIVE AND BRANCHED VEGETATIVE SHOOTS

of generations: an asexual phase, represented by a sporophyte (the horsetail plant, as commonly known), and a sexual phase, the gametophyte, or prothallus, an inconspicuous, delicate, green plant. Each year thousands of prothallia are probably initiated from spores, but very few survive in nature because they are killed by direct exposure to sunlight. In the United States they have been found on the shaded side of deep-cut streams or in abandoned quarries. Horsetails apparently survived as a small group of very ancient plants mainly by vegetative reproduction rather than by a regular dependence on an alternation of sexual and asexual generations. It is assumed that fossil members had an alternation of generations, although only sporophytes have been described for them.

Generally, horsetails are 30 in. or less in height. In the tropics, however, taller species are known. Accounts are given of specimens of *Equisetum giganteum* of the American tropics that attain heights of 10–12 yd. but that have a diameter of less than an inch. By contrast, a Mexican species 2 yd. in height may have a diameter of up to 4 in. The internodes are ridged and grooved. In certain living species (*E. arvense*, *E. telmateia*, etc.) the whorled leaves are arranged in a toothed sheath but are without chlorophyll; photosynthesis is accomplished in the green stems.

The horsetails have had little economic importance. In years past they have been used for scouring dishes and utensils of diverse kinds; their cleaning value is attributed to the silica in the walls of the epidermal cells. Undoubtedly, the scouring rushes, as certain species were known, were beneficial in removing tarnish and dust from metallic surfaces, but the silica is equally hard on the metal itself.

In reproduction, some horsetails have terminal, conelike strobili on aerial branches that later become vegetative. Other species, however, have separate, upright, aerial branches for vegetative and for reproductive shoots. In the latter, the strobilate branches appear first, and after the spores are shed, the green, vegetative shoots develop. Fertile appendages are whorled; each consists of a stalk bearing a flattened disk at its apex, on the inner side of which is found a cycle of sporangia, each opening and shedding spores by a longitudinal slit on its inner side. (The Carboniferous, tree-like horsetails and their sphegnoid allies are believed to have possessed the most elaborate reproductive strobili known among the vascular plants.)

The delicate spores, under low light intensity, grow into small (up to 3 cm. in diameter), flattened, green bisexual prothallia with upright lobes. The outer spore wall regularly breaks into four bands, which are hygroscopic and so coil and uncoil with moisture changes. Entangled by bands, the spores are frequently shed in clusters.

The slender, herbaceous stems of *Equisetum* have hollow internodes; the whorled leaves are greatly reduced and are united laterally at each node to form a toothed sheath around the stem. Each leaf has a single unbranched midvein. In the extinct order of climbing sphegnoids, the Sphenophyllales, the leaves were wedge shaped with a dichotomous (repeatedly forking) venation system. Species of the extinct giant horsetails, the Calamitales, were trees up to 1 m. in diameter and 30 m. in height. The linear leaves were whorled in arrangement. Secondary growth was characteristic of the Calamitales and Sphenophyllales. In *Equisetum* the vascular strands are organized into a cylinder surrounding a large pith cavity. In the majority of species, the cell walls of the epidermis are thick and contain silica deposits. Roots arise at nodes of underground stems (rhizomes). Branch buds also are initiated at nodes, but their subsequent growth is dependent on the growth characteristics of the particular species. In relatively unbranched species, the bud primordia remain inhibited.

The sporophyte consists of stem, leaves, and roots; spores are produced in spore cases, or sporangia. Sporangia are borne on special stalked structures termed sporangiophores. The latter are organized into strobili associated with sterile bracts (Sphenophyllales, Calamitales) or without them (Hyeniales, Equisetales). Each sporangium in *Equisetum* has five to ten recurved sporangia. The entire sporangiophore appears to be a condensed dichotomous branch system, each sporangium occupying the end of a branch

but lying parallel to the stalk of the sporangiophore. Eggs are produced in archegonia, at the bases of the upright lobes on the small gametophytes, and sperm are produced in antheridia, present on the lobes. The egg is fertilized in the archegonium by a multi-flagellate sperm; then the zygote, by continued divisions, forms an embryo within the archegonium. The embryo (young sporophyte) is nourished by the gametophyte until it develops its own shoot and roots. One gametophyte may support two or more young sporophytes before it ultimately dies and decays.

The report of a chromosome number of about 216 for a horsetail sporophyte gives some support to the contention that the genus *Equisetum* is the end of a long line of specialization and possibly represents the oldest living genus of vascular plants.

**SPHERE**, in Greek geometry, the solid generated by the revolution of a semicircle about its diameter as an axis. In modern elementary geometry it is more generally considered as the spherical surface so generated, or as the locus of points at a constant distance from a fixed point called the centre. The constant distance is called a radius, and any line segment through the centre and limited at both ends by the sphere is called a diameter. Any section made by a plane cutting a sphere is a circle, called a great circle if the plane passes through the centre, and otherwise a small circle. The solid cut off by the plane of a great circle is a hemisphere; that cut off by the plane of a small circle, a segment. In analytic geometry the equation of a sphere in rectangular Cartesian coordinates with centre at the origin is  $x^2 + y^2 + z^2 = a^2$ , where  $a$  is the radius, and in polar coordinates it is  $r = a$ . If the centre is  $(\alpha, \beta, \gamma)$ , the Cartesian equation becomes

$$(x - \alpha)^2 + (y - \beta)^2 + (z - \gamma)^2 = a^2$$

The surface area of a sphere is  $4\pi r^2$ , and the volume is  $\frac{4}{3}\pi r^3$ . See ANALYTIC GEOMETRY; CIRCLE; SOLIDS, GEOMETRIC; SURFACES; TRIGONOMETRY.

**SPHERE OF INFLUENCE**, a diplomatic term that signifies a claim by a state to exclusive control within a foreign territory. This control can be economic, military, or political, or it may concern the overall government of the territory. The territory that is made the object of a sphere of influence may be either politically unorganized, as were some of the African territories that were transformed into spheres of influence toward the end of the 19th century, or it may be under the sovereignty of a weak government, as were, for instance, Morocco, Ethiopia, and Persia when they were divided into spheres of influence at the beginning of the 20th century. The term may refer to a political claim to exclusive control, which other nations may or may not recognize as a matter of fact, or it may refer to a legal agreement by which another state or states pledge themselves to refrain from interference within the sphere of influence.

It is in the latter, legal significance that the term first gained currency in the 1880s when the colonial expansion of the European powers in Africa and Asia was nearing its completion. The last stage of that expansion was characterized by the endeavour of all major colonial powers to carry on the mutual competition for colonies peacefully through agreed-upon procedures. Agreements on spheres of influence served this purpose. Thus, the agreement between Great Britain and Germany in May 1885, the first to make use of the term, provided for "a separation and definition of their respective spheres of influence in the territories of the Gulf of Guinea." In it "Great Britain engages not to make acquisitions of territory, accept Protectorates, or interfere with the extension of Guinea which lies east of" a defined line. "Germany engages not to make acquisitions, accept Protectorates, or interfere with the extension of British influence in that part of the coast and interior of Guinea which lies between the line as above described . . . and the British Colony of Lagos. Both Powers agree to withdraw all Protectorates which they have already established within the limits hereafter assigned to the other party . . . Germany declares herself ready . . . to refrain from making acquisitions of territory or establishing Protectorates on the coast between the Colony of Natal and Delagoa Bay."

This agreement was followed by many of a similar nature, of

which article vii of the agreement between Great Britain and Germany of July 1, 1890, concerning East Africa may be regarded as typical. Its text is as follows: "The two Powers engage that neither will interfere with any sphere of influence assigned to the other by Articles I to IV. One Power will not in the sphere of the other make acquisitions, conclude Treaties, accept sovereign rights or Protectorates, nor hinder the extension of influence of the other. It is understood that no Companies nor individuals subject to one Power can exercise sovereign rights in a sphere assigned to the other, except with the assent of the latter."

Agreements of this type concerned territories politically unorganized and therefore subject to occupation by whatever nation complied with the rules of international law relative to the acquisition of unoccupied territory. Agreements of another type, often called spheres of interest, refer to territories that are already politically organized and are to be transformed into a sphere of influence of one of the contracting parties. This type is exemplified by article ii of the Anglo-French agreement of April 8, 1904, concerning Morocco. It provided: "The Government of the French Republic declare that they have no intention of altering the political status of Morocco. His Britannic Majesty's Government, for their part, recognize that it appertains to France, more particularly as a Power whose dominions are continuous for a great distance with those of Morocco, to preserve order in that country, and to provide assistance for the purpose of all administrative, economic, financial, and military reforms which it may require. They declare that they will not obstruct the action taken by France for this purpose. . . ."

Of the legal effects of such agreements, three are worthy of note. First, agreements establishing spheres of influence create rights and obligations between the contracting parties only. States that are not parties to the agreement are legally free to acquire within the sphere of influence whatever rights they can; they have, however, for political reasons generally refrained from interference and acted as though they, too, were bound by the agreement. Second, such agreements do not affect by themselves the actual control over the territories concerned. So long as the state in whose favour a sphere of influence has been established chooses not to exercise its exclusive rights within that sphere, the actual control over it remains in the hands of those who exercised it when the agreement was concluded. Third, once the state in whose favour a sphere of influence has been established makes use of its rights within that sphere, all states, whether or not they are parties to the agreement, are excluded from the territory to the extent that the former state exercises actual control.

When colonial expansion came to a close with World War I, spheres of influence in the legal sense lost much of their importance. From then on, the term was used more for the unilateral political claims of great powers to a predominant position in the territories of other nations, especially those adjacent to their own. Thus, it can be said that the Monroe Doctrine, especially in its application since the presidency of Theodore Roosevelt, established the Western Hemisphere as a sphere of influence for the United States. In the aftermath of World War II, the Soviet Union created a sphere of influence as a political fact in the territories of the nations of eastern Europe and of the Balkans, with the exception of Greece (and later Yugoslavia). The political division of the Balkans into spheres of influence in the political sense was foreshadowed in the agreements concluded between Great Britain and the Soviet Union in 1944 and on the face of it was intended only to facilitate military operations and not to outlast the war. These agreements were opposed by U.S. Secretary of State Cordell Hull, who was not "a believer in the idea of balance of power or spheres of influence as a means of keeping the peace" (from Cordell Hull, *The Memoirs of Cordell Hull*, vol. ii, p. 1452, copyright 1948 by Cordell Hull, the Macmillan Company, 1948). The intervention of the United States in Santo Domingo in 1965 was justified by some observers on the ground that the island lay within the U.S. sphere of influence. Regardless of one's evaluation, it seems that spheres of influence in the political sense are an inevitable concomitant of the struggle for power among sovereign nations. See INTERNATIONAL LAW, PUBLIC; MONROE DOCTRINE.

See Frederick L. Schuman, "Regionalism and Spheres of Influence," in Hans J. Morgenthau (ed.), *Peace, Security and the United Nations* (1946). (H. J. Mv.)

**SPHERICAL HARMONICS** are special mathematical functions that find application in mathematical physics to theories of gravitation, electricity and magnetism, fluid motion, and other fields; in geometry to the theory of surfaces; and in mathematical analysis to some classes of partial differential equations. They were named spherical harmonics by Lord Kelvin.

The gravitational potential in a portion of space free of masses, the electrostatic potential in a portion of space free of electric charges, and many other physical variables  $R$  satisfy Laplace's equation

$$\Delta R = \frac{\partial^2 R}{\partial x^2} + \frac{\partial^2 R}{\partial y^2} + \frac{\partial^2 R}{\partial z^2} = 0 \quad (1)$$

Solutions of equation (1) are known as harmonic functions (see DIFFERENTIAL EQUATIONS, PARTIAL; FUNCTION: Analytic Functions of a Complex Variable). A (solid) spherical harmonic (of degree  $n$ ) is a homogeneous harmonic function of the Cartesian coordinates  $x, y, z$ . If the spherical coordinates  $r, \theta, \phi$  are introduced by

$$x = r \sin \theta \cos \phi, y = r \sin \theta \sin \phi, z = r \cos \theta$$

a spherical harmonic  $R_n$  of degree  $n$  can be expressed in the form  $R_n(x, y, z) = r^n S_n(\theta, \phi)$ , where  $S_n$  satisfies the partial differential equation

$$\frac{\partial^2 S}{\partial \theta^2} + \cot \theta \frac{\partial S}{\partial \theta} + \csc^2 \theta \frac{\partial^2 S}{\partial \phi^2} + n(n+1) S = 0 \quad (2)$$

and is known as a spherical surface harmonic of degree  $n$ . All spherical surface harmonics are homogeneous functions of degree zero of the Cartesian coordinates  $x, y, z$ .

If  $R_n(x, y, z)$  is a spherical harmonic of degree  $n$ , then  $(x^2 + y^2 + z^2)^{-n-1} R_n(x, y, z)$  is a spherical harmonic of degree  $-n-1$ . Solid spherical harmonics are closely related to Laplace's equation; spherical surface harmonics arise in connection with a variety of partial differential equations. They arise in connection with Laplace's equation not only in spherical but also in spheroidal and conical coordinates (spheroidal harmonics and ellipsoidal surface harmonics, respectively). In the latter case their occurrence is due to the circumstance that the natural affine mapping of an ellipsoid onto a sphere carries the partial differential equation of ellipsoidal surface harmonics into equation (2). In spherical coordinates, spherical surface harmonics arise not only in connection with equation (1) but also in connection with: Poisson's equation  $\Delta V = f(x, y, z)$ , where  $f$  is a given function; the equation  $\Delta V + f(r)V = 0$ , where  $f$  is a given function depending only on  $r$ , and where special solutions of the partial differential equation have the form  $F(r)S_n(\theta, \phi)$ , with  $F$  satisfying the ordinary differential equation

$$\frac{d^2 F}{dr^2} + \frac{2}{r} \frac{dF}{dr} + \left[ f(r) - \frac{n(n+1)}{r^2} \right] F = 0$$

while  $S_n$  satisfies equation (2); the wave equation

$$c^2 \Delta V = \frac{\partial^2 V}{\partial t^2}$$

governing wave motion in many physical theories; the diffusion equation

$$k \Delta V = \frac{\partial V}{\partial t}$$

governing conduction of heat as well as many other diffusion processes; Schrödinger's equation in quantum mechanics (*q.v.*); and other partial differential equations.

There are spherical harmonics in spaces of several dimensions, but this discussion will be restricted to the most important class of spherical harmonics: those for which  $n$  is a nonnegative integer and  $R_n(x, y, z)$  is a homogeneous polynomial (of degree  $n$ ). In this case, the corresponding spherical surface harmonic  $S_n(\theta, \phi)$  is a polynomial (*q.v.*) in  $\cos \theta, \sin \theta, \cos \phi$ , and  $\sin \phi$ .

**Properties of Spherical Harmonics.**—The integral

$$\int_{-\pi}^{\pi} g(x \cos u + y \sin u + iz, u) du$$

represents a general solution of Laplace's equation (E. T. Whittaker, 1902). In particular, with an integrable function  $f(u)$ ,

$$\int_{-\pi}^{\pi} (x \cos u + y \sin u + iz)f(u) du \quad (3)$$

represents a polynomial spherical harmonic of degree  $n$ , and every such spherical harmonic can be represented in the form of integral (3). The representation is not unique.

Let  $c_n$  be a constant, let  $h_1, h_2, \dots, h_n$  be  $n$  directions in space (not necessarily distinct), and let  $\frac{\partial}{\partial h}$  denote directional differentiation in the direction  $h$ . Then

$$c_n r^{n+1} \frac{\partial^n}{\partial h_1 \partial h_2 \dots \partial h_n} \frac{1}{r} \quad (4)$$

represents a polynomial spherical harmonic of degree  $n$ , and every such spherical harmonic can be represented in this form. The representation is essentially unique. A curve on the unit sphere at the points of which a spherical harmonic (or the corresponding surface harmonic) vanishes is known as a nodal line of that spherical harmonic (surface harmonic). If the  $n$  directions in spherical harmonic (4) coincide, the system of nodal lines consists of  $n$  circles of latitude that divide the unit sphere into zones; this is a zonal spherical harmonic. If the  $n$  directions are situated in a plane at angles of  $\pi/n$ , there are  $n$  nodal circles of longitude that divide the sphere into sectors, and the corresponding spherical harmonics are known as sectorial spherical harmonics. Lastly, if  $n-m$  directions coincide in a direction known as the axis, and the remaining  $m$  directions are situated in the plane perpendicular to the axis and are at angles  $\pi/m$ , then there are  $m$  nodal circles of longitude and  $n-m$  nodal circles of latitude that divide the sphere into spherical rectangles, and the corresponding harmonics are known as tesseral spherical harmonics (see SPACE EXPLORATION: *Effect of Asymmetrical Bodies*).

Any linear combination of spherical harmonics of a fixed degree  $n$  is again a spherical harmonic of that degree. There are  $2n+1$  linearly independent (polynomial) spherical harmonics of degree  $n$ . One set of  $2n+1$  linearly independent spherical harmonics whose axis is the  $z$  axis is given by

$$R_n^m(x, y, z) = r^n S_n^m(\theta, \phi) = \frac{(-1)^{n-m}}{(n-m)!} r^{n+1} \frac{\partial^{n-m}}{\partial z^{n-m}} \left( \frac{\partial}{\partial x} \pm i \frac{\partial}{\partial y} \right)^m \frac{1}{r} \quad (5)$$

where  $m = 0, 1, \dots, n$  and either upper or lower signs must be taken throughout equation (5).  $R_n^m \pm R_n^{-m}$  is a zonal, sectorial, or tesseral harmonic according as  $m = 0$ ,  $m = n$ , or  $1 \leq m \leq n-1$ . Any polynomial spherical harmonic of degree  $n$  can be represented uniquely as a linear combination of the  $2n+1$  functions of equation (5).

Any solution of equation (1) that is twice continuously differentiable inside a sphere around the origin can be expanded (inside that sphere) in an infinite series  $\sum_{n=0}^{\infty} r^n S_n(\theta, \phi)$ . Any solution of equation (1) that is twice continuously differentiable outside a sphere about the origin and that vanishes at infinity can be expanded (outside that sphere) in an infinite series  $\sum_{n=0}^{\infty} r^{-n-1} S_n(\theta, \phi)$ .

In both cases, the expansions are unique.

The spherical coordinates  $\theta, \phi$  determine a point on the unit sphere. For two functions  $f$  and  $g$  on the unit sphere there can be defined a scalar product

$$(f, g) = \int_0^{\pi} \int_{-\pi}^{\pi} f(\theta, \phi) \bar{g}(\theta, \phi) \sin \theta d\theta d\phi$$

where  $\bar{g}$  is the complex conjugate of  $g$ . These two functions are said to be orthogonal if  $(f, g) = 0$ . Spherical surface harmonics are functions on the unit sphere. Any two spherical surface harmonics of different degrees are orthogonal. The spherical surface

harmonics  $S_n^m(\theta, \phi)$ ,  $m = -n, -n+1, \dots, n$ ;  $n = 0, 1, 2, \dots$ , defined by equation (5) form an orthogonal system (see FOURIER SERIES: *Orthogonal Series*) in the sense that  $(S_n^m, S_{n'}^{m'}) = 0$  unless  $m = m'$  and  $n = n'$ . This orthogonal system is complete in the sense that a continuous function (on the unit sphere) that is orthogonal to all the  $S_n^m$  vanishes identically. With any integrable function  $f$  on the unit sphere is associated the Laplace expansion

$$\sum_{n=0}^{\infty} \sum_{m=-n}^n C_{nm} S_n^m(\theta, \phi) \text{ where } C_{nm} = \frac{(f, S_n^m)}{(S_n^m, S_n^m)}$$

Under suitable conditions (for instance, if  $f$  is continuous and continuously differentiable on the unit sphere), the Laplace expansion will converge to  $f$ .

$$\text{Let } \cos \gamma = \cos \theta \cos \theta_0 + \sin \theta \sin \theta_0 \cos(\phi - \phi_0) \quad (6)$$

be the spherical distance of the two points  $(\theta, \phi)$  and  $(\theta_0, \phi_0)$  on the unit sphere, and let  $K(w)$  be a fixed function that is continuous for  $-1 \leq w \leq 1$ . Then every spherical surface harmonic satisfies

$$\int_0^{\pi} \int_{-\pi}^{\pi} K(\cos \gamma) S_n(\theta, \phi) \sin \theta d\theta d\phi = \lambda_n S_n(\theta_0, \phi_0)$$

where  $n$  is the degree of  $S_n$ .

$$\lambda_n = 2\pi \int_{-1}^1 K(w) P_n(w) dw$$

and  $P_n(w)$  is the Legendre polynomial of degree  $n$  (see below).

**Legendre Polynomials.**—The reciprocal distance of the two points  $(x, y, z)$  and  $(0, 0, 1)$  is a solution of equation (1) that is infinitely differentiable inside the unit sphere; it therefore has an expansion in spherical harmonics that is convergent inside the sphere. In terms of the spherical coordinates  $r, \theta, \phi$  of the point  $(x, y, z)$  the expansion clearly does not contain  $\phi$  and hence is of the form

$$\frac{1}{\sqrt{1-2r \cos \theta + r^2}} = \sum_{n=0}^{\infty} r^n P_n(\cos \theta), \text{ where } r < 1 \quad (7)$$

It turns out that  $P_n(\cos \theta)$  is a zonal spherical surface harmonic that is a polynomial of degree  $n$  in  $\cos \theta$ .  $P_n(\cos \theta)$  is called the Legendre polynomial of degree  $n$ . Substituting equation (7) in equation (1), it is seen that  $P_n(w)$  satisfies Legendre's equation

$$(1-w^2) \frac{d^2 P}{dw^2} - 2w \frac{dP}{dw} + n(n+1)P = 0 \quad (8)$$

and indeed can be characterized as that solution of equation (8) that is equal to unity when  $w = 1$ . An explicit representation of the Legendre polynomial is furnished either by Rodrigues' formula

$$P_n(w) = \frac{1}{2^n n!} \frac{d^n}{dw^n} (w^2 - 1)^n$$

or by Laplace's integral

$$P_n(\cos \theta) = \frac{1}{2\pi} \int_{-\pi}^{\pi} (\cos \theta + i \sin \theta \sin u)^n du$$

There are also numerous explicit representations in terms of hypergeometric series (see FUNCTIONS, SPECIAL).

All  $n$  zeroes of  $P_n(w)$  are simple, real, and between  $-1$  and  $1$ . The Legendre polynomials form an orthogonal system on the interval  $(-1, 1)$ ,

$$\int_{-1}^1 P_n(w) P_{n'}(w) dw = \begin{cases} 0 & \text{if } n \neq n' \\ \frac{1}{n+\frac{1}{2}} & \text{if } n = n' \end{cases}$$

This orthogonal system is complete, and with every integrable function  $f(w)$ ,  $-1 \leq w \leq 1$ , there is associated a Legendre series

$$\sum_{n=0}^{\infty} c_n P_n(w) \text{ where } c_n = (n+\frac{1}{2}) \int_{-1}^1 f(t) P_n(t) dt$$

The series converges to  $f(w)$  under suitable conditions.

$P_n(w)$  is an even or odd function of  $w$  according as  $n$  is even or odd. Legendre polynomials of different degrees are connected by numerous functional relations, including

$$\begin{aligned}(2n+1)wP_n(w) &= (n+1)P_{n+1}(w) + nP_{n-1}(w) \\ (w^2-1)\frac{dP_n(w)}{dw} &= (n+1)P_{n+1}(w) - (n+1)wP_n(w) \\ &= nwP_n(w) - nP_{n-1}(w)\end{aligned}$$

The complete solution of Legendre's equation is  $aP_n(w) + bQ_n(w)$ , where  $a$  and  $b$  are constants, and

$$Q_n(w) = P_n(w) \int_w^\infty \frac{1}{t^2-1} \frac{1}{[P_n(t)]^2} dt$$

is the Legendre function of the second kind.

**Associated Legendre Functions.**—It can be shown that the spherical surface harmonics defined in equation (5) are of the form

$$S_n^m(\theta, \phi) = P_n^m(\cos \theta) e^{\pm im\phi} \quad (9)$$

where  $P_n^m(\cos \theta)$  is  $\sin^m \theta$  multiplied by a polynomial in  $\cos \theta$  of degree  $n-m$  and is called an associated Legendre function of degree  $n$  and order  $m$ . Substituting equation (9) in equation (2), it is seen that  $P_n^m(w)$  satisfies the associated Legendre equation

$$(1-w^2)\frac{d^2P}{dw^2} - 2w\frac{dP}{dw} + \left[n(n+1) - \frac{m^2}{1-w^2}\right]P = 0$$

Associated Legendre functions can be expressed in terms of Legendre polynomials in the form

$$P_n^m(w) = (-1)^m (1-w^2)^{m/2} \frac{d^m P_n(w)}{dw^m} \quad (10)$$

and in particular,  $P_n^0(w) = P_n(w)$ .

Explicit representations and many properties of associated Legendre functions follow readily from corresponding properties of Legendre polynomials by means of equation (10). In particular, the only zeros of  $P_n^m(w)$  are  $n-m$  real simple zeros between  $-1$  and  $1$ ; furthermore,  $w = \pm 1$  if  $m \geq 1$ . For fixed  $m$ , associated Legendre functions form an orthogonal system and

$$\int_{-1}^1 P_n^m(w) P_n^m(w) dw = \begin{cases} 0 & \text{if } n \neq n' \\ \frac{1}{n+\frac{1}{2}} \frac{(n+m)!}{(n-m)!} & \text{if } n = n' \end{cases}$$

Associated Legendre functions arise also in the addition theorem of Legendre polynomials,

$$\begin{aligned}P_n(\cos \gamma) &= P_n(\cos \theta) P_n(\cos \theta_0) + \\ &\sum_{m=1}^n \frac{(n-m)!}{(n+m)!} P_n^m(\cos \theta) P_n^m(\cos \theta_0) \cos m(\phi - \phi_0)\end{aligned}$$

where  $\cos \gamma$  is given by equation (6).

A general solution of the associated Legendre equation can be given as  $aP_n^m(w) + bQ_n^m(w)$ , where

$$Q_n^m(w) = (1-w^2)^{m/2} \frac{d^m Q_n(w)}{dw^m}$$

is the associated Legendre function of the second kind.

Legendre functions and associated Legendre functions exist also for general (not necessarily integral) values of  $n$  and  $m$ ; these are connected with nonpolynomial spherical harmonics and will not be discussed here.

**Rotations.**—A rotation of three-dimensional space can be characterized by three angles called the Euler angles;  $R(\alpha, \beta, \gamma)$  denotes the rotation characterized by the angles  $\alpha, \beta, \gamma$ . All rotations of three-dimensional space form a group  $R(3)$  (see Groups). For each natural number  $n = 1, 2, 3, \dots$ ,  $R(3)$  has exactly one irreducible representation of dimension  $n$ . (A representation of a group is a mapping of the group onto a group of matrices so that multiplication is preserved in the mapping. Such a representation is reduced if the matrices can be partitioned in such a manner that the block in the upper right-hand corner is the zero matrix; and the representation is irreducible if it cannot be

transformed into a set of reduced matrices by a [fixed] similarity transformation. The number of rows in each of the matrices involved in the representation is called the dimension of the representation.) The irreducible representation  $\Gamma_j$  of dimension  $2j+1$ ,  $j = 0, 1/2, 1, 3/2, \dots$  maps the rotation  $R(\alpha, \beta, \gamma)$  into the matrix whose element in the  $m$ th row and  $m'$ th column is

$$\begin{aligned}D_{mm'}^{(j)}(\alpha, \beta, \gamma) &= \left[ \frac{(j+m)!}{(j-m)!} \frac{(j-m')!}{(j+m')!} \right]^{1/2} e^{i(m\alpha + m'\gamma)} \\ &\times (\cos \frac{1}{2}\beta)^{m+m'} (\sin \frac{1}{2}\beta)^{m-m'} P_{j-m}^{(m-m')}(\cos \beta)\end{aligned}$$

Here  $m, m' = j, j-1, j-2, \dots, -j$ , and

$$P_n^m(x) = \frac{(-1)^m}{2^n n!} (1-x)^{-n} (1+x)^n \frac{d^n}{dx^n} [(1-x)^{n+1} (1+x)^{n+1}]$$

is Jacobi's polynomial. These matrix elements can be shown to be four-dimensional spherical surface harmonics.

The representations of odd dimensions  $2n+1$ ,  $n = 0, 1, 2, \dots$  are generated by the normalized spherical surface harmonics

$$\begin{aligned}Y_n^m(\theta, \phi) &= (-1)^m \left[ \frac{2n+1}{4\pi} \frac{(n-m)!}{(n+m)!} \right]^{1/2} S_n^m(\theta, \phi) \\ m &= 0, 1, 2, \dots \\ Y_n^m(\theta, \phi) &= \left[ \frac{2n+1}{4\pi} \frac{(n+m)!}{(n-m)!} \right]^{1/2} S_n^m(\theta, \phi) \\ m &= -1, -2, \dots\end{aligned}$$

in the sense that

$$Y_n^m(\theta', \phi') = \sum_{m'=-n}^n D_{mm'}^{(n)}(\alpha, \beta, \gamma) Y_n^{m'}(\theta, \phi)$$

if the rotation  $R(\alpha, \beta, \gamma)$  carries the point  $(\theta', \phi')$  on the unit sphere into the point  $(\theta, \phi)$ .

Define the direct sum of two matrices,  $A = [a_{kl}]$  of order  $M$  and  $B = [b_{rs}]$  of order  $N$ , as the partitioned matrix

$$\begin{bmatrix} A & 0 \\ 0 & B \end{bmatrix}$$

of order  $M+N$ , and the Kronecker product  $A \times B$  (see ALGEBRA, [LINEAR]) as that matrix of order  $MN$  whose element in the row labeled  $kr$  and the column labeled  $ls$  is  $a_{kl}b_{rs}$ . This underlies the Clebsch-Gordan expansion, stating that the direct product of the irreducible representations of dimensions  $n$  and  $n'$  is similar to the direct sum of all the irreducible representations whose dimensions  $n''$  satisfy  $|n-n'| \leq n'' \leq n+n'$ . The elements of the similarity transformation involved here are the Clebsch-Gordan coefficients.

**SPHEROID**, literally a spherelike body. In geometry the term is applied to figures generated by an ellipse (*q.v.*) revolving about either its minor axis (giving an oblate spheroid) or its major axis (giving a prolate spheroid). If the equation of the generating ellipse is  $b^2x^2 + a^2y^2 = a^2b^2$ , and the ellipse revolves about the major axis (the  $x$  axis), the volume is  $\frac{4}{3}\pi ab^2$ ; if about the minor axis, it is  $\frac{4}{3}\pi a^2b$ . The equation of the prolate spheroid is  $b^2x^2 + a^2(y^2 + z^2) = a^2b^2$ ; that of the oblate spheroid is  $b^2(x^2 + z^2) + a^2y^2 = a^2b^2$ . See ELLIPSOID.

**SPHERULITE**, in petrology, is a small rounded body which commonly occurs in vitreous igneous rocks. Spherulites are often visible in specimens of obsidian, pitchstone and rhyolite as globules about the size of millet seed, with a duller lustre than the surrounding glassy base of the rock, and when they are examined with a lens they prove to have a radiate fibrous structure.

Spherulites are commonest in acid glassy rocks but occur also in basic glasses such as tachylyte. Sometimes they compose the

whole mass; more usually they are surrounded by a glassy or felsitic base. Occasionally spherulites have zones of different colours, and while most frequently spherical they may be irregular in outline. In some New Zealand rhyolites the spherulites send branching "cervicorn" processes (like stag horns) outward through the surrounding glass of the rock. Long, elliptical or bandlike spherulites are called axiolites.

Large cavernous spherulites have been called lithophysae; they are found in obsidians at Lipari, Italy, Yellowstone National park, etc. The characteristic radiate fibrous structure is usually conspicuous, but the fibres are interrupted by cavities which are often so arranged as to give the spherulite a resemblance to a rosebud with folded petals separated by arching interspaces. Some of these lithophysae are one inch or more in diameter. Spherulites with typical radiate fibrous structure may be produced in artificial glasses, salt solutions and melts of organic substances. Their study reveals the existence of an equatorial constriction perpendicular to a line along which the growth of the original sheaf of fibres began. New fibres grow at an angle to previous fibres so that the sheaf opens up at both ends, and fibres finally meet along the equator. A cavity is left, shaped like a flattened doughnut, but it is filled by later crystallizations. (J. D. H. D.)

**SPHINX**, a composite creature with lion's body and human head. The name is Greek and the sphinx is famous in Greek legend. According to Apollodorus she was a winged, human-headed lion, offspring of two giants, who lived in the vicinity of Boeotian Thebes. She terrorized the people by demanding the answer to a riddle taught her by the Muses—what is it that has one voice and yet becomes four-footed and two-footed and three-footed?—and devouring a man each time the riddle was answered incorrectly. Eventually Oedipus gave the proper answer: man, who crawls on all fours in infancy, walks on two feet when grown and leans on a staff in old age; the sphinx thereupon killed herself. From this tale apparently grew the legend that the sphinx was omniscient, and even today the wisdom of the sphinx is proverbial. The word *sphinx* was derived by Greek grammarians from the verb *spingein* (to bind or squeeze), but the etymology is not related to the legend and therefore dubious. The earliest form was apparently *phix*, for which no etymology has been suggested; probably the word was not originally Greek.

In ancient near eastern art the monster is well known. The earliest example is one of the most famous monuments of all antiquity, the colossal recumbent sphinx at Giza, in Egypt, dating from the reign of King Khafre (Chephren) of the 4th dynasty, c. 2550 B.C. This is known to be a portrait statue of the king, and the sphinx continues as a royal portrait type through most of Egyptian history, symbolizing both the mighty strength and the protective power of Egypt's ruler. Through Egyptian influence the sphinx became known in Asia, especially in the Levant in the 2nd millennium B.C., where it became a popular subject on cylinder seals and other forms of decorative art. Its meaning in Asia is uncertain; it is no longer a royal portrait but may share with its Egyptian counterpart a certain protective aspect. Asian art always showed a fondness for monstrous beings, and the Egyptian sphinx may have been added to the repertory merely as another kind of monster. Although Mesopotamia was the place of origin of many monsters, the sphinx does not occur there until around 1500 B.C., when it was clearly imported from the Levant. In appearance the Asian sphinx differs from its Egyptian model most noticeably in the addition of wings to the leonine body, a feature that continues through its subsequent history in Asia and the Greek world. Another innovation is the female sphinx, which appears in the 14th century B.C. A few are found in Egypt in the 18th dynasty but it is common in the Levant, which is probably its homeland. What meaning the change of sex may have had is uncertain, but both males and females are found in similar poses and seem to play the same role in art. On seals, ivories and metalwork they sit on their haunches, often with one paw raised, and are frequently paired with a lion, a griffin or another sphinx.

Around 1600 B.C. the sphinx first appeared in the Greek world. Seal impressions and other objects from Crete at the end of the Middle Minoan period and from the shaft graves at Mycenae at

the beginning of the Late Helladic Age show the sphinx, characteristically winged, and in the later part of the Late Helladic Age (14th and 13th centuries) the creature appears frequently on ivories, metal plaques and painted pottery. Although clearly derived from the Asian sphinx, the Greek examples are not identical in appearance; they customarily wear a flat cap with a flamelike projection on top. Nothing in their context connects them with the later legend and their meaning at this time is unknown.

HIRMER FOTOARCHIV MÜNCHEN

GREEK SPHINX OF THE ARCHAIC PERIOD, FROM DELPHI. IN THE DELPHI MUSEUM, GREECE

Around 1200 B.C. came the cataclysm in both Greek and Asian lands that marks the division between the Bronze and Iron Ages; it is traditionally known in Greece as the Dorian invasion and in Asia as the invasion of the Sea Peoples. For about 400 years no sphinxes appeared in Greece, but in Asia they continued in forms and poses similar to those of the Bronze Age. By the end of the 8th century the sphinx reappeared in Greek art and was common through the orientizing and Archaic periods (down to the end of the 6th century). It is often associated with griffins, lions and other oriental motifs and is clearly derived from the same source; from its appearance it cannot be a direct descendant of the Bronze Age Greek sphinx.

The new Greek sphinx is almost always female and usually wears the long-tiered wig known on contemporary sculptures of the Daedalic style; the body becomes graceful and elegant in line and the wings develop a beautiful curving form unknown in Asia. Sphinxes decorate vases, ivories, and metal works and in the late Archaic period occur as ornaments on temples. As in the Bronze Age, the context is usually insufficient to enable their meaning to be judged, but their appearance on temples (especially the large terra-cotta acroteria on a 6th-century Artemis temple at Calydon) suggests a protective function. The handsome stone sphinx atop a votive column set up by the Naxians in the Apollo precinct at Delphi corroborates a sacred meaning of some sort, as does the use of the sphinx on sepulchral monuments. By the 5th century clear illustrations of the Oedipus legend appear on vase paintings, usually with the sphinx perched on a column (e.g., the red-figured Nolan amphora in Boston), but other monuments of classical age show Oedipus in armed combat with the sphinx and suggest an earlier stage of the legend in which the contest is physical instead of mental. Of such a stage the literature gives no hint, but battles of men and monsters are common in Asian art from prehistoric times down to the Achaemenid Persians, and Greek art may have adopted from the near east a pictorial theme that Greek literature did not share.

**SPHRANTZES, GEORGE** (1401—end of the 15th century), Byzantine historian and diplomat, wrote a chronicle covering the years 1413-77. He rose to high office in the service of Manuel II and the later Palaeologan rulers, both in Constantinople and in the Peloponnese. In 1451 Sphrantzes was great logothete (chancellor) in Constantinople and on its capture by the Ottomans he fled to Mistra and then had to retreat to Corfu, where he and his wife finally entered monastic life (1468). His chronicle is probably what is known as the *Chronicon Minus* and not the *Chronicon Maius*. The *Chronicon Maius*, considered by some to be Sphrantzes' expansion of the *Minus*, was probably compiled later by Macarius Melissenus. The chronicle was written for the Corfiotes and deals with the last years of the Palaeologi in Con-

stantinople and the Peloponnese, and it shows marked aversion to the Ottomans and the Latins.

The *Chronicon* was edited by I. Bekker in *Corpus scriptorum historiae Byzantinae*, xxiii (1838), and in J. P. Migne, *Patrologia Graeca*, vol. 156 (1866). A critical edition of books i-ii was made by J. B. Papadopoulos (1935).

**SPIDER**, an invertebrate animal, the best known of the arachnids, is an eight-legged relative of the insects. Spiders form the order Araneae of the class Arachnida (q.v.). They attract attention by the webs they spin; and though they all spin silk, not all of them live a sedentary existence on a web. Superstitions surround them. Spider folklore includes admiration for their skill, wisdom, and cunning; fear of their sinister appearance, habits, and venomous qualities; and belief in their ability to influence the weather and in their medicinal value. The taxonomic scheme followed in this article differs from that given in the article ARACHNIDA, where more suborders are proposed for the group here known as Araneomorphae.

### GENERAL FEATURES

**Diversity and Habits.**—Spiders are ancient animals, some of which seem little changed from their ancestral fossil forms. They are now found around the world—from the polar regions to the tropics—in a great variety of habitats: on the ground, ballooning high in the air, in caves, on mountains, and even in water.

The bird spiders and allies (suborder Mygalomorphae) are more generalized than the true spiders (suborder Araneomorphae), and have become specialists in unusual ways of living. The burrowing trap-door spiders and the purseweb spiders are mygalomorphs that live in specially constructed lairs. The true spiders are a highly varied, abundant, and conspicuous group. The diurnal jumping spiders actively pursue their prey, whereas the orb weavers spin a complex web in which they remain quietly until their prey becomes ensnared.

While most spiders are encountered out-of-doors, many dwell within human habitations, where, despite their insectivorous habits, they are not always welcome. Other species live on or near the ground (family Gnaphosidae) and may make tunnels or hide in natural cavities. The trap-door spider lines his excavation with silk and has a silk-hinged door covering it. Some forms live among the dead leaves and litter of the forest floor. Others are found in tall grass, on bushes and trees. While some, like the ground spiders and the wolf spiders (Lycosidae), may be found running over the ground, actively pursuing prey, others, like the orb weavers (Argiopidae) and funnel-web spiders (Agelenidae), are encountered lying in wait in or near their webs.

While it is not unusual for spiders to resemble their background, there are forms that resemble insects, pieces of bird dung, bud

scales, pieces of grass or straw, or plant galls. Some species mimic ants, not only in appearance but also in behaviour.

The variation in colour is wide, from the sombre dark grays and browns of ground spiders to the bright flower-mimic colours displayed by the sedentary crab spiders (Thomisidae) and the zebra-stripping of the jumping spiders (Salticidae).

The largest species known are certain hairy bird spiders (family Theraphosidae), popularly called tarantulas in America; in tropical American jungles these spiders may be more than 3 in. in body length and have a leg span of more than 10 in. While their bites are painful and their appearance fearsome, they are not dangerous to man. Among the smallest spiders are species of *Microlinyphus*, whose members are under  $\frac{1}{16}$  in. long. Most spiders, however, have bodies that range in length between  $\frac{1}{8}$  and 1 in.

**Economic Importance.**—It is difficult to assess the value of the predation done by spiders in any biotic community. However, they are often present in such enormous numbers that their overall effect must be significant. Various estimates place the number of spiders in a given area as follows: about 264,000 spiders per acre of forest floor in Barro Colorado Island, Panama Canal Zone; 2,265,000 per acre in undisturbed meadow in England; and 14,000 per acre on herbs and shrubs of woodland in Illinois.

### STRUCTURE AND FUNCTION

Like most arachnids, spiders are distinguished from insects by the subdivision of the body into two portions: the cephalothorax and the abdomen. The cephalothorax is a result of the fusion of the head with the thorax. This fusion is so nearly complete that the outlines of the head may be recognized only from the shallow depression (cervical groove) that separates its dorsal surface from that of the thorax. The abdomen is attached to the cephalothorax by a very slender waist, the pedicel.

**External Features.**—The body wall of spiders, like that of other arachnids, is an exoskeleton formed of chitin. Movements are possible because of the membranous character of the joints. The exoskeleton is important both for protection and attachment of muscles. Within the body are chitinous skeletal elements that also serve as points of attachment for muscles. The most important of these is the endosternite found within the cephalothorax.

The cephalothoracic shield, or carapace, is quite uniform in appearance. Above, it is usually a smooth, convex surface, but more often there is a slight cervical groove. Behind the cervical groove, many species have another conspicuous depression or pigmented line, the dorsal, or thoracic, furrow or groove. There may be three pairs of less conspicuous radial furrows behind the cervical groove. The underside of the cephalothorax is formed of two unequal chitinous plates, the sternum and the labium, or lip, the latter being one of the mouthparts.

The eyes, present at the anterior portion of the carapace, are simple ocelli like those of insects. Most spiders have four pairs, though some families have only six eyes. There are a few species in which the eyes are completely lacking. In most families, the eyes are arranged in two rows, enclosing a space called the eye area, or ocular quadrangle. Between the anterior row of eyes and the edge of the carapace is the area termed the clypeus. The relative size and placement of the eyes, and the width and inclination of the clypeus, are often important features for classifying spiders.

Below and in front of the clypeus are the paired chelicerae, used for seizing and holding prey. Each of these consists of a heavy basal section, the paturon, and a smaller distal segment, the fang. The paturon often bears a small nipplelike tubercle, and its outer surface many have a series of ridges forming a stridulating organ. The fang, usually sickle shaped, is formed of very hard chitin. The concave edge is grooved, and the lower or posterior edge is usually toothed. Near the tip of the fang is the opening of the poison gland. The opening is in a protected position and is thus prevented from being closed as the spider drives its fangs into its prey.

The second pair of appendages are the palpi (or pedipalpi), which serve different functions. Among the young and females they act as sensory organs, while in the mature male the femur

may be used in stridulation and the tarsus is an accessory to the reproductive system. Each palpus has six segments: the coxa, trochanter, femur, patella, tibia, and tarsus. The basal segment, the coxa, is expanded in most spiders to form the maxillary mouthparts. Between the two maxillae is the labium. The maxilla, separated by a membrane from the coxa of the limb, is used to compress food particles and squeeze their liquid contents into the pharynx.

The tarsal segment of the male palpus serves as a sexual intromittent organ. The male palpal tibia also is different from that of the female. It is relatively shorter, and frequently has a short process on its outer side. In its simplest form, the palpal organ is situated near the tip of the tarsus in a cavity, the alveolus. The palpal organ is formed of a coiled tube with three recognizable parts: the proximal swollen bulb, an intermediate reservoir, or fundus, and a dark, elongated ejaculatory duct. From this simple condition more complex palpi have developed. In one type, the genital bulb is on the lower side of the palpus.

The palpal organ is divisible externally into basal, middle, and apical divisions. In the most complex type, the apical division (or embolus) of the genital bulb is divided into two parts. One of these, the duct through which the sperm passes, is considered the embolus proper. The other division is the conductor that functions to protect the embolus when it is in position in the alveolus.

There are always four pairs of legs, each consisting of seven segments: coxa, trochanter, femur, patella, tibia, metatarsus, and tarsus. Each segment is a chitinous cylinder united by a membrane to the adjoining one, and each, except the femur, is straight. The coxa is nearest the body. The femur is curved in some species. There are at least two claws at the end of each tarsus, and in some there is an unpaired, median ventral third claw. Usually the legs are covered with hairs; in addition there may be spines, bristles, and even scales. Among some species, one or more pairs of tarsi or metatarsi are provided with a dense brush of stiff hairs, the scopula. The spider often uses its legs for purposes other than walking. For example, the first leg, usually the longest, is an important organ of touch. Among some male spiders, it is quite elaborate and is used for display before the female during courtship.

The abdomen of spiders is very diverse. In some species it may bear colourful patterns or designs. Usually the male is more colourful than the female. The shape of the abdomen may vary considerably, with forms like the spiny-bodied spiders of the genus *Micrathena* having a bizarre appearance. The undersurface of the abdomen, near the pedicel, is more convex and is termed the epigastrum. It is separated from the rest of the abdomen by the

epigastric furrow. The openings of the book lungs lie on either side of the epigastric region, and the reproductive organs open between them. The single opening of the united sperm ducts (paired interiorly) of the male spiders is small and difficult to discern. The paired oviducts of the female, however, have large apertures closely associated with the single or paired openings of the seminal receptacles, which receive and store the sperm of the male. The area surrounding the seminal receptacles, the epigynum, is quite diverse in its form and appearance.

Also present on the abdomen are the spinnerets, modified appendages of the fourth and fifth abdominal embryonic segments that are supplied with silk-producing glands. These glands open at the end of specially modified hairs, the so-called spinning tubes situated on the spinnerets. In some species, the total number of spinning tubes has been estimated to be as high as 1,000, in others it is less than 100. The cribellate spiders have a flat spinning organ, the cribellum, a sievelike plate in front of the anterior spinnerets. Associated with the cribellum is another structure, an accessory comb of hairs, the calamistrum, found on the metatarsi of the hind legs.

**Sense Organs.**—The body and legs, pedipalpi, chelicerae, and even the spinnerets are covered with numerous hairs of various kinds, some stiff and stout, others slender and pliable, some smooth, others provided with serrations. Some are sensory in function, each tactile hair having its own nerve fibre that conveys impulses to the central nervous system. Especially fine, erect hairs arising from the centre of little drumlike membranes are sensitive to slow currents of air. These hairs formerly were suspected of detecting sound vibrations. While some spiders have sound-producing organs, no organs of hearing have been found among spiders.

The anterior median eyes of the spider have a direct retina; the other eyes have an inverted retina and are often supplied with a tapetum of pigment cells, reflecting light and giving the eyes a pearly appearance. The disposition of the eyes is characteristic of whole families and is responsible for the diverging directions of the axes of the eyes. Convergent eyes do not occur in spiders. The respective fields of vision are determined by the shape and curvature of the lens; the acuity of vision is determined by the diameter and size of the image, and the distance at which the image of two points falls on a single rod. Each pair of eyes forms images of a size different from that formed by the other eyes and the fields of vision are mostly quite different. The best spider eyes have lenses with spherical surfaces, but the acuity of vision with even the best eyes is far below that of human eyes.

The olfactory sense is very poorly developed and apparently restricted to what one may call sexual odours. The males of some species are able to follow the scent left by a female on a smooth surface, such as a sheet of paper. Other scents apparently are not perceived unless the substance is of a highly irritating nature.

**Feeding and Digestion.**—Spiders are solitary predators that subsist on the juices of the prey. After subduing its prey, the spider injects it with digestive juices and then sucks the liquefied product into the mouth, which lies directly above the labium and in close contact with a flattened cone of tissue, the rostrum. The lower surface of the rostrum is covered with a chitinous plate, the epipharynx. A corresponding plate, the hypopharynx, is found on the upper surface of the labium.

The alimentary system of the spider is quite complex and consists of three main portions: the foregut, midgut, and hindgut. Only the midgut is lined with epithelium and is absorptive.

The foregut consists of the pharynx, esophagus, and gizzard, all lined with chitin, the same as that of the body wall with which they are continuous. The pharynx arises almost vertically between the epipharynx and the hypopharynx. It acts both as a pump and strainer, preventing coarse particles from passing into the esophagus. The hypopharynx is merely a tube connecting the pharynx with the gizzard, which is also a pump. The pharyngeal gland, a small oval mass of secretory cells located in a space resulting from the curvature of the epipharynx, has a duct leading to the end of the pharynx, near its junction with the esophagus.

The midgut has two functions: to produce enzymes for the digestion of foods, and to absorb the digested foods. The absorptive surface is increased in the cephalothorax by several branched sacs, or diverticula. After the digestive tube passes through the pedicel, and shortly before entering the abdomen, it curves upward and widens. The upper surface of this wider portion usually has four openings, which lead into the complex series of branched tubules known as the abdominal gland. This gland occupies the greater portion of the spider's abdomen and is penetrated by the excretory tubules. It appears to act as a digestive gland and also as a reservoir, permitting the spider to ingest large amounts of food at one time. This food is stored and gradually absorbed by the abdominal gland. The midgut also forms a large pouch, the stercoral pouch, in which wastes are stored before being excreted. The midgut passes into the hindgut, with little or no change in size. The rectum is a straight tube opening at the anus, which lies at the end of a small tubercle.

**Respiration.**—For respiratory exchange, spiders have book lungs and tracheae, occurring either separately or together. Most spiders, however, have a pair of book lungs and either a single or a paired tracheal opening. The book lungs can be seen as pale patches in the epigastric region. Actually each is a large hollow space that opens to the outside by means of a small pore. Within the space there are from 15 to 20 "leaves," each actually a fold of the body wall; therefore, each is double and the two halves are separated by many vertical supports. The top surface of the upper lamella of each fold has vertical knobbed spikes that separate the leaves and allow air to circulate freely. The blood sinuses of the abdomen communicate with the hollows within the leaves. The tracheal spiracle opens just in front of the spinnerets. The tracheae diverge in bunches at intervals from a main tube. Air diffuses directly from the lumens of the tracheae into the tissues adjoining them.

**Blood and Associated Tissues.**—The space between the alimentary canal and the body wall is almost entirely filled with blood and is known as the hemocoel. Within this cavity lie the organ systems of the spider. A true body cavity, such as that of the vertebrates, is confined to small spaces in the gonads and in the excretory glands.

The blood of the spider contains clear, rounded corpuscles, or leucocytes, floating in plasma that contains the respiratory pigment hemocyanin, similar to hemoglobin but bearing copper rather than iron. When the spider's blood is deprived of oxygen, it is colourless; oxygenated blood has a pale but pronounced blue tinge due to oxyhemocyanin.

The spider possesses a circulatory system in which the blood is in the blood vessels only during a portion of its course through the body. The heart, a straight tube lying in the dorsal portion of the abdomen, is surrounded by a thin-walled sac, the pericardium. The space between the heart and the sac, the pericardial space, is filled with blood, which enters the heart through three or four pairs of openings or ostia. The ostia have valves that prevent the blood from returning to the pericardium from the heart. Leading forward from the heart, the aorta dips down and passes through the pedicel into the cephalothorax and gives off the posterior dorsal vessels that supply the muscles of the anterior region. Behind the stomach, the aorta divides into two branches that lie between the sides of the stomach and the cephalothoracic diverticula. Other blood vessels arise from the aortic vessel and supply the organs of the cephalothorax. A series of lateral arteries arising from the heart supply the organs of the abdomen. Posteriorly, the heart continues as the caudal artery. The blood is collected in channels, then delivered to sinuses, of which there are six, three in each major portion of the body. The sinuses conduct the blood to the book lungs where it is oxygenated. The blood then flows back to the pericardium by means of the pulmonary veins.

**Excretion.**—Malpighian tubules and coxal glands are the main organs for the excretion of nitrogenous waste products. The tubules are a pair of fine branches opening into the intestine near the stercoral pouch. The uric acid secreted by these tubules appears to be in the form of sodium urate. The coxal glands, found near the first and third legs, discharge their products into

a convoluted tube whose many coils occupy the area from the first to fourth coxae. The convoluted tube is lined with excretory epithelium, but does not excrete solid material. From its posterior end, a straight tube runs forward, giving off short exit tubes to the outside behind the first and third coxae.

The degree of development of this excretory system varies greatly in the different families. It is generally believed that the coxal glands represent modified nephridia (primitive excretory organs) and that various silk and poison glands have developed from similar glands in other parts of the animal.

**Nervous System.**—The nervous system is concentrated in the cephalothorax. During early development, a pair of ganglia is present in each segment of the body, but later the ganglia consolidate into a single mass surrounding the esophagus. The supraesophageal portion of the nervous system, above the esophagus, is considered the brain. The optic nerves and the nerves of the chelicerae arise from it. Below the esophagus is the subesophageal ganglion, broadly joined with the supraesophageal ganglia to form a nerve collar around the esophagus. From the subesophageal ganglion arise nerves extending to the pedipalpi and legs. The visceral nervous system consists of an unpaired nerve running along the esophagus and stomach. It is connected with the brain by paired nerves. Ganglia associated with the ventral nerve cord have also been considered as being part of the visceral nervous system.

**Reproduction.**—The tubular testes of the male are in the abdomen, just below the alimentary tract. Anteriorly, the testes are continued into the much coiled sperm ducts. These latter unite eventually to form the short seminal vesicle, which leads to the single median opening located in the epigastric furrow. The ovaries are located in a position similar to that of the testes, but they are much larger. Superficially they resemble a diminutive bunch of grapes because of the ovarian follicles projecting from their surfaces. The eggs pass through the neck of the follicle into a space within the ovary. From this space they travel into the oviducts, straight tubes that unite to form the uterus and the vagina. The chitin-lined vagina leads directly to the epigynum. Two narrow ducts lead laterally from the vagina to the seminal receptacles. In some spiders there are separate receptacular openings also found on the epigynum.

## LIFE CYCLE

**Eggs and Their Care.**—The female prepares a silken sheet upon which the eggs are laid. As she passes the eggs one by one from her genital opening, sperms, stored in a syrupy fluid in the seminal receptacles, are spread over them. Since the eggs have a very soft covering, they are easily penetrated by the sperm at any point. The number of eggs laid varies greatly: some tiny species lay only a very few eggs at a time, others up to 300; the average number is about 100. After the eggs are laid, the female covers them with a silken sheet and molds them into the egg sac characteristic of her species. Many of these sacs are beautifully designed, and the care given them by the female varies. Wolf spiders drag the sac behind them, then later carry the young on their backs; some spiders divide the risk of losing their eggs by placing them in a series of sacs that are hung in the centre of their snare or are left singly in different places.

**Development.**—The development of the spider within the egg is similar to that of other arachnids. The spiderling gradually takes form on the outer surface of the egg. In the area that becomes the cephalothorax, little buds appear. These gradually differentiate into chelicerae, palpi, and legs. Similar buds appear on the abdominal portion of the embryo with a rather definite division into 8 to 12 segments. All buds behind the sixth true segment disappear. The buds of the fourth and fifth segments develop into the spinnerets, those on the second and third segments form the book lungs. When the embryo finally encircles the outside of the egg and the ventral surface is outside, a process called reversion occurs. This reverses the position of the embryo and frees the cephalothoracic region. At about this same time, the expanding embryo presses against the chorion and by the use of its egg tooth (at the base of the palpi) ruptures the egg cover. The resulting

minute spiderlike creature, the deutovum, is still surrounded by embryonal membranes. While still in the egg sac it grows rapidly and toward the end of this stage becomes visible. The first true molt takes place in the sac, after which the animal is known as a spiderling. The spiderling is able to feed, though it still uses the yolk in the abdomen, and it can spin. In favourable weather, the spiderlings escape from the sac, usually by tearing it open, and disperse. They may remain in the egg sac throughout the winter, then disperse in the spring when the weather is favourable.

**Growth.**—From time to time during its growth, the spider must molt. The American tarantulas spin a sheet of silk upon which they lie during the whole process. The true spiders often hang in their webs or in retreats. The freshly molted spider, very pale and soft, hardens and darkens gradually. All growth occurs during this short instar period. The number of molts necessary to attain maturity varies from species to species. Small species molt only a few times, while large ones molt several times. Large bird spiders may molt more than 20 times. The males of the black widow spider (*Latrodectus mactans*) become adult between the fourth and seventh molts; the females are adult after the seventh to ninth molt.

**Life Span.**—The spiders of the temperate zones usually live only one year. There are actually two groups, one of which is represented by over-wintered or recently matured males that become abundant in early spring and are on hand for the maturing females. In the late summer and early fall, another group of spiders mature and become conspicuous. The eggs they lay have substantial sacs and are more heavily insulated than those of the spring spiders. Their young either spend the winter in the cocoon or under debris.

In general, the male spider does not live so long as the female. In the northern United States, a wolf spider may live several years. It appears that many of the mygalomorph spiders live for several years. The males of the bird spiders mature in 8 or 9 years, but usually die a few months later, while females in captivity have been known to live for more than 20 years.

**Behaviour.**—Spiders have attained a prominent position in the world without benefit of intelligence. Their behaviour, while amazingly complex, is wholly instinctual. They perform their tasks like automatons.

**Spinning and Webs.**—The spider is an inveterate spinner throughout its life. Its silk, used for many different purposes, is a scleroprotein produced as a liquid. When drawn out of the spinnerets, it ordinarily hardens to form the threads. The mechanical stretching of the silk during the drawing of the lines, not exposure to the air, is responsible for the hardening. Spider silk is both strong and elastic, its tensile strength being, second to that of fused quartz. If the threads are drawn out rapidly, they are stronger, for the fibroin chains then attain a maximum orientation. There are several types of spider silk that vary in strength and elasticity.

While spider threads may appear to be single fibres, they actually are not. The finest single fibre is about one-millionth of an inch in diameter. Much thicker threads, however, do occur. Most spider threads are formed of strands from several glands.

Whenever the spider moves about, it spins a silken line behind it. This is the dragline, which may be anchored at intervals much in the way that a mountain climber lets out a rope as he moves down a precipitous slope. An anchor is made by pressing the spinnerets against an object. The dragline is the fundamental thread of most spinning. The spider can use the dragline to "balloon" for great distances. The spiderling shortly after hatch-

ing climbs upward on tall grass or other upright object and turns toward the direction of the wind. It then extends its legs and tilts the abdomen upward. The threads from the spinnerets are drawn out by the air currents, and when the pull on the threads is strong enough, the spiderling lets go and is pulled into the air. Apparently, spiders are capable of traveling great distances in this manner, for they have been reported as landing on ships up to 200 mi. from land. While ballooning occurs all during the year, it seems to be most conspicuous in the fall.

Silk is also used for spinning egg cocoons, sperm webs, molting sheets, gossamer threads, attachment discs with cables, linings of burrows, hinges for trap doors, and for web snares of various types.

Most complex of these spinning products are the webs, of several types, more or less characteristic of spider families: sheet webs, funnel webs, tube webs, reticular webs, geometric orb webs, etc. The most complex snares are those of the geometric orb weavers (family Argiopidae). A finished web consists usually of three or four outer foundation lines, several inner foundation lines, many radial lines, a central hub, an intermediate zone, and a viscid spiral. Many species build a tent of silk or of a leaf rolled up and held together by threads of silk. In this tent, the spider hides during the day, holding in its claws the guy line connected with the centre of the web by which means the spider can detect vibrations caused by entangled insects. Species of *Argiope* weave additional X-shaped bands called stabilimentum, although they have nothing to do with stabilizing the web. Some weave a disc of lacework in the middle of the orb. *Cyclosa conica*, a little orb weaver common in both Europe and America, suspends in the diameter of its web a series of silk pellets to camouflage the egg cocoon, which occupies a place in the same row.

Many spiders build tents that are used as retreats or hiding places in which they find shelter from rain, cold, light, and enemies, or from which they can pounce upon unsuspecting victims. The Eurasian aquatic spider (*Argyroneta aquatica*) builds its tent under water in the shape of a bell and fills it with air. Special tents are often used for molting. Some females make complete envelopes of tough silk for themselves and their brood and stay inside until all the spiderlings are able to take care of themselves. Some species winter in special tents made for that purpose under the bark of trees.

Egg cocoons also show a great variety of structure. Some are circular or oval and perfectly flat; others are globular and smooth. Most cocoons are made with at least two walls. First the spider spins a sheet, deposits the eggs in it, covers them with another sheet and binds the two together, neatly clipping the edge. Then the outer sheet is made, often of a much tougher silk.

Silk is used for ensnaring insects captured in a snare. This makes their escape impossible and serves to store them as food for use at a later time. In case the insect is a dangerous adversary, such as a wasp or hornet, silk may be squirted as far as an inch from the spinnerets, a distance sufficient to make the combat safe.

(LEFT) LYNWOOD H. CHACE FROM NATIONAL AUDUBON SOCIETY, (RIGHT) R. B. HOIT—PHOTO RESEARCHERS, INC.

In their methods of capturing prey, spiders show great diversity. The sheet-web weavers (family Dipluridae) utilize a maze of threads extending in all directions and tied to adjacent vegetation. At the centre is a domelike sheet. Flying insects strike the high threads, then drop upon the dome, where the spider trusses them up. One typical orb weaver, *Mastophora*, is known as the boleadora, for it uses miniature bolas weighted with a quantity of viscid silk to capture its prey. One South African spider constructs a snare about the size of a postage stamp. The corners are held by the spider's long legs, and when an insect approaches, the web is stretched and hurled over the prey.

**Courtship.**—Courtship and mating habits of spiders are remarkable. The male is smaller than the female and approaches her with caution, for he may be perceived by her as a choice edible object. Recognition and acceptance are, therefore, very important preliminaries to courtship. Spiders with good vision make use of visual signs, while shortsighted and nocturnal species use contact stimuli. Before the male can mate, he charges his modified palp with semen. To do this, he weaves a small pad of silk, deposits a drop of semen upon it, and sucks it up with the palpus. The charged palpus is inserted into the seminal receptacle of the female during copulation. Each species has a palpus with a distinctive shape, and the correspondence of the epigynum with the palpal structure is such that pairing is probably possible only between males and females of the same species or closely related ones. The small male, if he escapes safely, may pair again after recharging his palpus.

**Regeneration.**—A spider can easily discard an appendage if it is injured. This process is termed autotomy. The limb can then be replaced by regeneration (*q.v.*).

**Poisonous Qualities.**—Poison glands, found in nearly all spiders, are associated with the chelicerae. Each chelicera has two segments, the stout basal segment and the movable fang. The poison gland may be entirely contained in the basal segment, but more often, it extends farther back into the head region. The poison flows from the gland and is released from a tiny opening near the end of the fang. When the spider bites, the fangs are forced into the victim's body. Two separate punctures are made, and, at the same time, muscles squeeze the glands and force the poison into the wound. The venom usually is a colourless liquid, and the amount injected at any one time is variable. Spider venom is very complex chemically and appears to contain both neurotoxins and hematoxins.

Fortunately, the venom of most spiders is feeble and its effects upon humans transitory. A few spiders, however, produce poisons that can cause severe local or general reactions in man. Members of the genus *Latrodectus* are generally regarded as being dangerous. In the United States the black widow spider (*Latrodectus mactans*) is notorious. Its bite often causes intense pain, followed by nausea, vomiting, faintness, tremors, and shock. Although the illness may seem grave, death is rare. The very young and older persons may be more seriously affected.

The bite of the brown recluse spider (*Loxosceles reclusus*) causes rather severe local reactions that may be followed by some general disturbance. This species lives in the midwest and south-central United States. Another member of this genus (*L. laeta*) is regarded as dangerous in portions of South America.

**Enemies.**—Many lizards, toads, and some birds feed upon spiders. Some solitary wasps, in particular, depend entirely upon spiders as food provision for their larvae. Some Hymenoptera and Diptera spend their larval life as external parasites of spiders. Nematodes are commonly found as internal parasites. While the

spider is molting, it is completely helpless and subject to attack by animals such as crickets, sowbugs, and mealworms, which at other times normally do not attack spiders.

### CLASSIFICATION

The two principal suborders of living spiders are the Mygalomorphae (bird spiders and allies) and the Araneomorphae (the so-called true spiders).

The mygalomorph spiders are more generalized in structure than the araneomorphs, and all live more than a single year. In general, they are quite large, averaging more than an inch in length. Their conspicuous chelicerae move in a vertical plane, a feature that distinguishes them from the true spiders. Two groups are recognized in this suborder. The first of these, the typical "tarantulas," includes the sheet-web spiders (Dipluridae) and the true trap-door spiders (Ctenizidae). They are most successful living underground. Very few are accomplished runners, jumpers, or climbers, and they do not rely on silk to capture prey as do the true spiders. The second group, the atypical "tarantulas," includes the purseweb spiders. These latter are very generalized and resemble fossil remains dating from the late Paleozoic.

The true spiders, members of the suborder Araneomorphae, are an enormous assemblage of highly varied forms, probably numbering about 40,000 species. In general, they are much smaller than the mygalomorphs, and their chelicerae move in a horizontal plane. The Araneomorphae is divided into seven main groups, each being further divided into families. These groups are the Hypochiloidea, the four-lunged true spiders; the Filistatoidea, the filistatids; the Dictynoidea, the typical cobweb spiders; the Plectruroidea, the primitive hunters and weavers; the Argioidea, the aerial web spinners; the Lycosoidea, the hunting spiders; and the Clubionioidea, the running spiders.

**SPILITE**, a fine-grained or dense igneous rock, usually free of visible crystals and commonly greenish or grayish-green in colour. Spilites are commonly vesicular (blistered) or variolitic (pocked) and show wonderfully preserved pillow structure, a feature in most cases indicative of a submarine origin of the lavas from which they were formed.

The individual pillows are filled with concentric zones of vesicles filled with chlorite and calcite. The formation of pillow structure in volcanic rocks was directly observed by the English volcanologist Tempest Anderson, joint author of the "Report to the Royal Society on West Indian Eruptions, 1902 and 1907," in the case of the lava poured into the sea from the volcano Matavanu in Samoa.

On the surface of the lava, buds form and expand, giving rise to "pillows" with a glassy crust. The interspaces between the pillows are frequently filled with sediment representing the soft ooze of the sea floor. Not all pillow lavas are spilitic.

The spilites are of basaltic character, but possessing in place of the normal labradorite, a feldspar of the composition of albite. The ferromagnesian mineral is an augite of pale brown colour; spilites are, however, usually very completely decomposed, augite being represented by chlorite and calcite.

Some spilites showing pillow structure are not strictly lavas but shallow intrusions into unconsolidated submarine ooze. Excellent examples of such intrusive spilites are provided by the Devonian spilites of Nundle, New South Wales. Though the term spilite was first used by Alexandre Brongniart (1770-1847) for altered basic lavas free from phenocrysts and possessing well-marked vesicular textures, early in the 20th century a new significance was given to the term by British geologists Dewey and Flett, who urged that a special group of rocks—the spilitic suite—should be recognized.

According to these authors, a large suite of igneous rocks is genetically associated with the spilites. Their composition varies widely, but they all have some characters in common. They possess a high percentage of soda and are usually extensively altered. These rocks are albite-dolerites, minverites, picrites, keratophyres, soda-felsites, and soda-granites. The spilitic suite was originally given a status comparable with that of the alkaline and calc-alkaline suites. The spilitic series is regarded as peculiar to districts that have undergone a long continued and gentle subsidence with few or slight upward movements and no important faulting.

The lavas are poured out on the margins of geosynclines while their common sedimentary associates are black shales, limestones, and radiolarian cherts. As geosynclines are the centres of subsequent fold movements many ancient spilites have become extensively folded and metamorphosed with production of new minerals, including albite of metamorphic origin. Eruptions having the spilitic facies have occurred repeatedly over a wide area and on a large scale.

(C. E. T.; X.)

**SPINA**, an ancient Etruscan port on the Adriatic coast of Italy, now about 6 mi. (10 km.) inland. It was situated on what were at the time of its foundation the coastal dunes at the mouth of a southern branch (the classical Sagis) of the Po River about 4½ mi. (7 km.) W of modern Comacchio. Spina was founded as a result of the Etruscan advance into north Italy in the closing years of the 6th century B.C., and throughout the 5th century it and Adria were the main ports of entry for the rich Greek commerce with northern Etruria. Soon after 400 B.C. Spina was sacked by the Gauls, and with the collapse of its market and the ruin of its port by the advance of the delta, it rapidly lapsed into obscurity.

The principal remains are the contents of the cemeteries of Valle Trebbia and of Valle Pega (excavated at intervals since 1922 in the course of land-reclamation schemes), now in the Museo Archeologico Nazionale, Ferrara. Nearly 2,000 graves have been recovered, yielding many fine bronzes and an unrivalled collection of Greek pottery, mainly red-figured vessels of Attic origin. The sites of the canal port and of the wharves and habitations alongside it have been revealed in great detail by air photography.

(J. B. W.-P.)

**SPINACH**, a hardy, leafy annual, *Spinacia oleracea*, of the family Chenopodiaceae, used as a vegetable. The large, edible leaves are arranged in a rosette, from which a seed stalk subsequently emerges. The leaves are somewhat triangular and may be flat or puckered.

The species is basically dioecious, with male flowers on one plant and female flowers on another, but monoecious plants occur with varying proportions of male and female (and sometimes perfect, or bisexual) flowers. There is some correlation between the sex expression and the leaf shape, the female forms tending to be associated with the broader-leaved and more commercially desirable types. Further, the more male types tend to bolt (produce a flower stalk) more easily than the female; hence, breeding work aimed at producing a large leaf crop combined with slow bolting has resulted in varieties with a predominance of female types.

The plant is wind pollinated, and the pollen is extremely small, so that elaborate precautions are needed by breeders to prevent unwanted cross-pollination.

Spinach requires cool weather, deep rich well-limed, well-watered soil to give quick growth and maximum leaf area and to discourage bolting. Seed can be sown every two weeks from early spring to late summer, in rows 12 in. apart, the plantlets being thinned to 6-8 in. in the row. The last sowings will produce young plants that yield a crop in the autumn and stand over the winter, providing leaves in early spring, or even through the winter if the weather should be not too severe. It is essential to have enough plants to permit picking only the largest leaves from each plant. If too many leaves are removed, bolting will be encouraged; picking little and often should be the rule.

Spinach, widely grown in the United States, Holland, and the Scandinavian countries, is marketed fresh, canned, or frozen. It received much publicity in the 1920s when attention was called to its relatively high content of iron and vitamins A and C. (The comic strip "Popeye" helped to overcome, particularly among children, a resistance to spinach based largely on its unusual flavour.) Although spinach is rich in calcium, it is also rich in oxalic acid, which combines with calcium. This makes the calcium nutritionally unavailable.

Spinach beet, or perpetual spinach (*Beta vulgaris cicla*), is one of the perennial leaf beets, with leaves larger and more fleshy than those of spinach and considered by many people to be more palatable. It stands hot weather much better than true spinach and should be treated in the same way as the garden beet, but it needs a rich soil in order to encourage the development of large foliage. Of less popularity are New Zealand spinach (*Tetragonia expansa*) and mountain spinach, or orach (*Atriplex hortensis*), coarse annual herbs whose tender young leaves produce greens similar to spinach when cooked.

(J. C. Ha.)

**SPINAL CORD** in man is the elongated cylindrical portion of the central nervous system located in the upper two-thirds of the vertebral canal of the vertebral column.

The reader who makes a close study of this article may be helped occasionally by consulting the related articles BRAIN; NERVE: *Spinal Nerves*; NERVE CONDUCTION; NERVOUS SYSTEM.

#### ANATOMY

The spinal cord is about 45 cm. (18 in.) long. It extends from just above the first cervical vertebra (atlas) at the base of the skull to the level of the first lumbar vertebra, where it is known as the conus medullaris. Small groups of nerve fibres that are attached to the spinal cord unite to form the segmental series of dorsal roots and ventral roots (fig. 1 and 2). One dorsal root and one ventral root combine in the region of an opening, the intervertebral foramen, between the two vertebrae to form one of the 31 pairs of spinal nerves. The dorsal roots contain the nerve fibres that transmit sensory impulses from the body to the spinal cord, while the ventral roots are composed of the motor fibres that transmit nerve impulses from the cord to the muscles and glands.

The spinal cord does not occupy the entire length of the vertebral canal because the vertebral column continues to grow after the cord has reached its full length. Since the column is longer than the cord, the nerve filaments of each dorsal root leave the cord above the site where the root enters the intervertebral foramen (fig. 1).

Each thoracic, lumbar, sacral, and coccygeal spinal nerve is named from the vertebra that is just above its exit from the vertebral column. As there are 12 thoracic vertebrae, 5 lumbar vertebrae, 5 fused sacral vertebrae, and 1 (to 3) vestigial coccygeal vertebra, there are 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal spinal nerves (fig. 1).

There are eight cervical nerves, although only seven cervical vertebrae, because in addition to a nerve passing below each cervical vertebra one exists above the first cervical vertebra. The long roots of the lower third of the vertebral canal below the conus medullaris form a structure called the cauda equina ("horse's tail").

**Meninges.**—The cord is enveloped by three coverings, the

BY COURTESY OF CIBA CLINICAL SYMPOSIA, VOL. 1, NO. 6, AND THE CIBA COLLECTION OF MEDICAL ILLUSTRATIONS

FIG. 1.—THE SPINAL CORD

meninges (figs. 1 and 2). From within outward they are the pia mater, arachnoid mater, and dura mater. These meninges are continuous with comparable layers surrounding the brain. The pia mater is closely attached to the spinal cord and contains the many blood vessels that supply the cord. The pia mater continues as a strand in the middle of the cauda equina known as the filum terminale, which extends to the coccyx (fig. 1).

The second meninx is the arachnoid layer, which is connected to the pia mater by delicate strands. The region between the two layers is the subarachnoid space, which is filled with the cerebrospinal fluid. Formed mainly in the brain, the fluid cushions the spinal cord. In the region caudal to (that is, below) the conus medullaris the arachnoid forms a cul-de-sac (fig. 1)—containing the cauda equina and cerebrospinal fluid—into which lumbar puncture needles are inserted to withdraw cerebrospinal fluid for diagnostic examination and to inject spinal anesthetics. This procedure avoids damage to the spinal cord, while injury to the spinal roots is minor.

The outer layer is the dura mater, a tough fibrous tissue surrounding the cord and continuous with the sheaths of the spinal roots and spinal nerves. It extends caudally to the lower sacral region where it is reduced to a strand, the filum duralis spinalis, attached to the coccyx (fig. 1). A thin subdural space is located between the dura mater and the arachnoid. Between the dura mater and the vertebral column is the epidural space, which contains many blood vessels, especially veins, and fat. A hypodermic needle may be inserted into this space in the lower sacral region for the injection of certain anesthetics (caudal anesthesia).

See also MENINGES AND CEREBROSPINAL FLUID.

**Cervical and Lumbosacral Enlargements.**—The spinal cord has two enlargements: the cervical enlargement and the lumbosacral enlargement. These regions are large because these segments are involved in the innervation of the upper and lower extremities respectively. The fifth through eighth cervical segments and the first thoracic segment comprise the cervical enlargement. The spinal nerves arising from the cervical enlargement form the brachial plexus (fig. 1).

**Cross Section.**—In cross section the spinal cord consists of an H-shaped gray matter surrounded by white matter (fig. 2 and 3). The gray matter is made up of cell bodies of nerve cells (the part of the cell containing the nucleus and other constituents) and nerve fibres oriented in the cross-sectional plane because the fibres enter and leave the gray matter from the white matter and spinal roots. The white matter consists of nerve fibres that are oriented parallel to the long axis of the spinal cord. These fibres are ascending to and descending from the brain and other levels of the spinal cord. The whiteness is due to the fatty sheath (myelin sheath) that surrounds many of the fibres. Some nonneural cells, called neuroglia, are scattered in both the gray matter and the white matter. The arms of the H that extend dorsally (that is, toward the back of the body) are called dorsal (sensory) horns, while the ventrally (toward the front) directed arms are called ventral (motor) horns. The crossbar of the H is the gray commissure and the intermediate gray. The gray matter is largest in the regions of the cervical and lumbosacral enlargements because of their relation to the innervation of the limbs. In the middle of the gray commissure is the small central canal, which is continuous with the ventricles of the brain. The white matter is subdivided into four columns: the dorsal column, between the dorsal horns; the ventral column, between the ventral horns; and the lateral columns, at the sides of the gray matter.

**Anatomical and Functional Organization of the Spinal Cord.**—This may be visualized by describing the orientation of the nerve cells of the spinal reflex arcs (see below, *Physiology*). For example, the withdrawal of the hand upon touching a hot stove before it is felt is a spinal reflex. The heat stimulates the terminal endings of the thermal neurons in the hand. The resulting impulses are transmitted by the fibres of these neurons through the peripheral nerves and dorsal roots into the dorsal horn. Each sensory nerve cell has its cell body in a dorsal root ganglion. Thus each nerve cell is a unit structure extending from its peripheral ending in the hand to its termination in the gray matter of the spinal cord.

BY COURTESY OF CIBA CLINICAL SYMPOSIA, VOL. 1, NO. 6, AND THE CIBA COLLECTION OF MEDICAL ILLUSTRATIONS

FIG. 2.—CROSS SECTION THROUGH THORACIC VERTEBRA ILLUSTRATING THE SPINAL CORD, VERTEBRA, MENINGES, AND ASSOCIATED STRUCTURES

In the dorsal horn the nerve fibres have synapses (junctions) with one or more other neurons. The second nerve cells in the arc are called internuncial, or intercalated, neurons; each has a cell body in the gray matter (fig. 3). Some internuncial neurons send axons into the ventral horn and synapse with the motor cells whose cell bodies are in this horn. The axons of the motor cells reach the voluntary muscles via the ventral roots and peripheral nerves. In short, the stimulus transmitted by a nerve goes to the spinal cord via a dorsal root into the gray matter, then to an internuncial cell, and finally to the motor cell and the voluntary muscle.

FIG. 3.—DIAGRAM OF CROSS SECTION OF THE SPINAL CORD ILLUSTRATING THE RELATIONSHIP OF THE SENSORY NEURON, INTERNUNCIAL NEURONS, AND THE MOTOR NEURON (ARROWS ON THE NEURONS INDICATE THE DIRECTION IN WHICH IMPULSES TRAVEL)

via the ventral root and the peripheral nerve. Since a series of three cells is involved, this is known as a three-neuron reflex. If the internuncial neuron is not involved, only two cells are in the series (two-neuron reflex).

In the knee-jerk reflex the sensory cells synapse directly with the motor neurons in the gray matter; it is, therefore, a two-neuron reflex. The internuncial neuron may cross over from the dorsal horn of one side to the ventral horn of the opposite side and synapse with motor cells. This is one means of coordinating one side with the other. An intersegmental reflex is a mechanism relaying impulses to higher and lower spinal cord levels to coordinate large areas of the body. The fibres of such internuncial neurons leave the gray matter and go up, down, or both (fibres may divide into two or more branches) to other spinal levels in that part of the white matter called the fasciculus proprius and comma tract (fig. 4) and reenter the gray matter to synapse with motor cells.

The white matter of the spinal cord contains nerve fibres that transmit most of the nerve impulses from the body (below the head) to the brain and from the brain to the body. Microscopic examination of the white matter does not give visible evidence of functional subdivisions. However, on the basis of numerous experimental data and examinations of spinal cords from persons with spinal injuries, the white matter can be partitioned into functional regions called tracts or pathways. A tract, or fasciculus, is a collection of nerve fibres having the same origin, function, and termination. Those fibres transmitting impulses toward the brain belong to sensory, or ascending, tracts; those transmitting impulses from the brain form motor, or descending, tracts.

**Pathways of Sensation.**—The sensations called proprioceptive sensations are transmitted by the fibres in the dorsal columns. These include position sense, pressure sense, vibratory sense, sense of movement, and stereognosis. Position sense is the quality that enables a person to know where the parts of his body are in space when his eyes are closed. Pressure sense is the quality of sensation that results from a deformation of the skin; hence it may be called deep touch. When the stem of a vibrating tuning fork is placed in contact with a bone the vibratory sense is appreciated. Stereognosis, or two-point discrimination, is the faculty of perceiving the weight, form, and shape of objects and of distinguishing the distance between two touch stimuli.

These senses are transmitted by fibres that pass from the peripheral nerves and dorsal roots into the dorsal horn of the spinal cord. These fibres with their cell bodies in the dorsal root ganglia have several branches in the gray matter. The shorter branches (collateral fibres) are utilized in the spinal reflex arcs. The main axon continues into the dorsal column to ascend in the column to the lower medulla of the brain. Two points of note are: (1) a fibre in the dorsal column is a part of the same neuron that was stimulated in the body, and (2) this fibre ascends on the same side of the spinal cord as it enters (does not cross the midline of the cord).

As a consequence, the sense of position of the toes, for example,

is carried by nerve cells that extend from the toes to the medulla without a synapse. In addition, injury to the dorsal column on one side of the cord will result in the impairment of the proprioceptive senses on the same side of the body below the level of injury. Each half of the dorsal column is divided into a fasciculus gracilis and a fasciculus cuneatus (fig. 4). The proprioceptive impulses from the lower half of the body, including the lower extremities, are carried in the fasciculus gracilis, while those from the upper half of the body, including the upper extremities but excluding the head, are carried in the fasciculus cuneatus.

Some light touch sensations (gentle brushing of skin by cotton) are transmitted by fibres in the dorsal column. In the medulla the fibres of each half of the dorsal column synapse with neurons in the nucleus gracilis and nucleus cuneatus. The neurons of these nuclei cross over to the opposite side of the medulla and pass upward to the thalamus (*q.v.*) of the brain, from which they relay to the cerebral cortex.

Pain (*q.v.*) and temperature sensations are transmitted by another pathway. The fibres from the periphery, in common with other sensory fibres, enter the dorsal horn of the spinal cord where their terminal branches establish reflex connections with other neurons. At the spinal level at which the fibres enter the cord they synapse with dorsal horn neurons. Some of these cells are relays in the reflex arcs. Other neurons from the dorsal horn send axons across the midline to the opposite side through the ventral white commissure (ventral to the gray commissure) to join the lateral spinothalamic tract in the lateral columns (fig. 4). This tract contains more fibres as it ascends in the spinal cord, for new fibres are added from each spinal level. The tract's name is based on the fact that the fibres of the pathway originate in the dorsal horn of the spinal cord and terminate in the thalamus on the opposite side of the brain. Crude pain and awareness of touch may be brought to consciousness in the thalamus. Impulses from the thalamus are relayed to the cerebral cortex.

In addition to the light-touch fibres of the dorsal column, noted above, some light-touch impulses take a different pathway. After entering the dorsal horn the axons transmitting light touch synapse with neurons whose axons cross the midline to join the ventral spinothalamic tract in the ventral column (fig. 4).

The symptoms resulting from injury to the spinal cord are a consequence of the course of these pathways. For example, if the right half of the spinal cord is cut at a midthoracic level, conscious proprioception would be lost on the right side of the body below the level of the lesion (right abdomen and the right lower extremity). Pain and temperature sensations would be lost on the left side of the body below the level of the lesion. Because of the dual course of their fibres, light touch would be diminished, but not necessarily lost, below the level of the lesion. Perception of sensations from regions above the cut would be unimpaired.

Some unconscious proprioceptive impulses relay from the gray

FIG. 4.—SCHEMATIC SECTION THROUGH THE SPINAL CORD SHOWING THE LOCATION OF IMPORTANT TRACTS (DARK SHADED AREAS INDICATE TRACTS FROM BRAIN TO CORD; LIGHTER AREAS, FROM CORD TO BRAIN; DORSAL AND VENTRAL HORNS CONSTITUTE GRAY MATTER)

matter of the cord via the spinocerebellar tracts of the same and opposite sides and terminate in the cerebellum (fig. 4). This part of the brain is known as an unconscious proprioceptive organ.

The precise course of the pathways for sensations from the viscera (heart, intestinal tract, kidney, and so forth) through the white matter of the cord is not known.

**Motor Pathways.**—In the ventral horn of the gray matter are large motor cells whose axons pass through the ventral roots to the spinal nerves. These neurons, which innervate the voluntary muscles, are called lower motor neurons. If these cells become non-functional, as in poliomyelitis, the muscles are deprived of their nervous stimulation and do not contract. These muscles waste away (atrophy) and do not respond to stimulation (areflexia). This paralytic condition is known as a lower motor neuron paralysis.

The lower motor neuron cells are innervated by neurons of the spinal reflex arcs and by the descending motor tracts of the white matter. These descending tracts from the brain may synapse directly with the motor cells, but usually intercalated neurons of the gray matter are interposed between the descending tracts and the lower motor neurons. Collectively the motor tracts of the white matter are known as upper motor neurons. Their cell bodies are in the brain. Two major subdivisions of these motor tracts are recognized: the pyramidal tracts, which are phylogenetically new, and the extrapyramidal tracts, which are phylogenetically old.

The lateral pyramidal tract, or lateral corticospinal tract (fig. 4), arises in the cerebral cortex of the opposite side and crosses over just as its fibres enter the spinal cord. The direct pyramidal tract, or ventral corticospinal tract, originates in the cerebral cortex and crosses over in the spinal cord. The extrapyramidal tracts include the motor tracts that arise in regions of the brain other than the cerebral cortex. However, these tracts do receive nerve impulses from the cerebral cortex as well as other parts of the brain.

The extrapyramidal tracts include: (1) the vestibulospinal tract, which transmits impulses from the vestibular (balance) mechanisms of the inner ear; (2) the bulbospinal tract, which arises from the medulla or bulb of the lower brain stem; (3) the sulcomarginal tract, a collection of fibres from several regions of the brain stem; (4) the rubrospinal tract (minor in man) from the red nucleus in the midbrain; and (5) the reticulospinal tract (in local association with the rubrospinal tract) from the reticular formation of the brain stem.

When a number of these motor tracts are damaged, an upper neuron paralysis may result. This contrasts with the lower motor neuron paralysis previously mentioned. The reflexes are exaggerated, there is loss of voluntary motion, and the extremities become spastic. The condition, called spastic paralysis, results because the muscles are under control of a spinal cord that still mediates spinal reflex arcs but is deprived of its normal innervation from the brain. Spastic paralysis resulting from an injury of the spinal cord is observed on the same side of the body as the lesion.

The complexity of the nervous system is illustrated, for example, by spinal reflex arcs innervating the voluntary muscles. The motor pathways of the central nervous system discharge on small motor cells in the ventral horn of the spinal cord (fig. 4). These nerve cells whose axonal processes leave the spinal cord through the ventral roots stimulate small muscle fibres in certain sensory endings (neuromuscular spindles) to contract. These activated spindles in the voluntary muscles send impulses via sensory fibres through the dorsal root back to the spinal cord to synapse with the motor cells of the ventral horn. These motor cells stimulate the voluntary muscles to contract. When the voluntary muscles contract sufficiently the sensory endings in the tendons are stimulated to send impulses via sensory fibres through the dorsal root back to the spinal cord to inhibit the motor cells of the ventral horn. In brief, the sensory endings in the muscle and tendon have a critical role in muscle activity.

**Autonomic Nervous System.**—The autonomic nervous system, which is concerned with the motor innervation of glands, blood vessels, and the viscera, has neurons in the gray matter. The nerve cells of the sympathetic division of this system have their

cell bodies in the lateral part of the intermediate gray, known as the intermediolateral cell column, of the thoracic and upper lumbar levels. Their axons leave the spinal cord through the ventral roots. The nerve cells of the spinal part of the parasympathetic division of this system have their cell bodies scattered in the gray matter of the midsacral levels. Their axons leave the spinal cord through the ventral roots. The sympathetic nervous system assists the body in meeting emergencies and stress. This includes increasing the rate and force of the heartbeat, the dilatation of the bronchial tubes of the lungs, and the inhibition of the motility and the secretory activity of the digestive system. The parasympathetic system contributes to the conservation of bodily energy. This includes decreasing the rate and force of the heartbeat, the constriction of the bronchial tubes, and the stimulation of the motility and secretory activity of the digestive system.

### EMBRYOLOGY

The nervous system is one of the first organ systems to develop. It differentiates as a long narrow strip of cells, the neural plate, on the dorsal surface of the early embryo. Each side of the plate grows rapidly, folds over, and fuses with its counterpart of the other side at the midline to form the neural tube with a cavity, the central canal.

During this process the cord sinks below the surface to become covered by embryonic skin. The cells lining the central canal (ependymal cells) differentiate into the nerve cells of the spinal cord and of the ganglia of the peripheral nervous system and, in addition, some neuroglia cells. In fetal life, the gray matter and the white matter are recognizable. If by some chance the fusion of the neural plate to form the neural tube is incomplete, the malformation known as spina bifida may occur.

### COMPARATIVE ANATOMY

In all the vertebrates the spinal cord is a tube with a central canal. In the jawless fishes (cyclostomes) the cord is flattened and the neurons are arranged as a pair of thin wings surrounded by unmyelinated fibres. In the sharks (elasmobranchs) the nerve fibres are myelinated, and hence the distinction between white matter and gray matter exists as in the higher vertebrates. In the amphibians the amount of gray matter increases to form the H configuration present in reptiles and mammals. In the reptiles and mammals the increase in the number of cells in the gray matter and of fibres in the white matter is significant. The basic patterns and topographical relations of the gray matter and white matter are similar in these forms. The quantitative increase is related to the complexity of the neural integrative mechanisms in the higher vertebrates.

As compared with the brain, the spinal cord is a conservative structure in vertebrate evolution.

### PHYSIOLOGY

The spinal cord is only a part of the nervous organ that throughout the length of the body forms the meeting place of the nerve paths arriving from and issuing to all regions with which nerve fibres communicate.

To gain a true point of view for understanding the working of the spinal cord it is necessary to refer to the general function of the nervous system in the bodily economy.

**Relation to General Nervous System.**—An animal of microscopic size may continue throughout its life to be constituted entirely by one single cell. Animals of larger bulk, although each begins its existence as a single-cell, attain their development by the multiplication of the original single cell, so that from it there comes to be formed a coherent mass of cells very many millions in number. In these multicellular animals each of the constituent cells is a minute organism, individually born, leading its own life (yet influencing other cells in countless subtle ways), and destined for individual death. The corporate power of the complex animal is the sum of the powers of those manifold individual existences, its cells, as they respond integrally to the organizational principle of the whole being.

Of the agencies which integrate the complex animal, one of the most potent is nervous action. A certain number of the unit cells composing the animal are specially differentiated from the rest to bind the whole together by nervous action. These specially differentiated cells are the nerve cells, or neurons. They constitute living threads along which waves of physicochemical disturbance are transmitted to act as releasing forces for the energy in distant cells.

It is characteristic of this nervous system, the system of neurons, that, although ramifying far and wide through the body, it is a continuum from end to end. The peripheral nerves are formed of bundles of neurons lying side by side, but these, although packed close together, are strictly isolated from one another as conductors and remain isolated throughout the whole length of the nerve.

The points of functional nexus of the neurons with one another are confined to one region only of the whole system. All their conductive connections with one another take place solely in the central nervous mass which constitutes the so-called central nervous system, a nervous organ extending axially along the length of the body midway between the body's lateral halves. Thither the neurons converge in vast numbers, those of each body segment converging to that fraction of the central organ which belongs to their body segment. The central nervous organ thus receiving these neurons is called, where it lies in the head, the brain; the rest of it is called in vertebrates the spinal cord, in worms and arthropods the nerve cord. The central organ not only receives neurons that converge to it from outside, but many of its own neurons thrust out their conductive arms from it as nerve fibres carrying nervous influence outward to regulate the activity of glands and muscles.

In the vertebrates the ingoing (afferent) neurons for each segment, and similarly the outgoing (efferent) neuron fibres, are collected into a segmental nerve. These are each attached to the spinal cord by two roots, one dorsal, consisting of the afferent fibres, the other ventral, consisting of the efferent fibres.

**The Reflex.**—The simplest complete reaction of the system is a reflex. There are many reflexes which are extremely complex, being built up of a number of simpler reflexes combined. A reflex is a reaction started by the environment acting as a stimulus upon some nerve which communicates the excitement to other nerves by connections with them in the central nervous organ. The excitement so generated and transmitted finally travels outward from the central organ by one or more of the efferent nerves and through these reaches muscles or glands, producing in them its final effect. The muscles and glands are from this point of view termed effector organs. The reaction is therefore "reflected" from the central organ. The nerve structures which include its trajectory are spoken of as a nervous arc.

The whole purpose of the central nervous organ is to bring afferent neurons into touch with efferent neurons. The whole purpose of reflex arcs is to bind one part of the organism to another part in such a way that what the environment is doing to the organism at one place may appropriately call forth or restrain movement or secretion in the muscles or glands wherever situated in the organism.

**Receptor Cells.**—There is one condition for the due performance of these reactions which is not provided by the nervous system itself. The afferent neurons are not in most cases so constituted as to be excitable themselves directly by the environment—for instance, they cannot be stimulated by light. Their amenability to the environment, their sensitization to environmental agencies, is effected by special cells adjunct to their peripheral ends. These cells form organs called receptors. They are delicately adapted to be stimulated by this or that particular agent and are classifiable into various species, so that each species is easily excited by a particular agent which is "adequate" for it, and is inexcitable or excitable only with difficulty by agencies of other kinds. Thus in the skin some receptors are adapted for mechanical stimuli (touch) and not for thermal stimuli, while others (cold spots, warm spots) are adapted for thermal stimuli and not for mechanical. As far as it is known, each afferent neuron is connected with receptors of

one species only. The receptors thus confer upon the reflex arcs selective excitability. Each arc is thus tuned to respond to certain stimuli, while other arcs not having that kind of receptor do not respond. The receptors, therefore, while increasing the responsiveness of the organism to the environment, prevent confusion of reactions (in-coordination) by limiting to particular stimuli a particular reaction.

**Proprioceptors.**—The system of neurons is thus made accessible to the play of the external world acting on the body. And in addition to those receptors, which are stimulated directly by the external world, there are others lying within the mass of the organism itself, which are excitable by actions occurring in the organism. These are called proprioceptors. They are distributed preponderantly in the muscles and structures functionally adjunct to muscle, such as joints, ligaments, fasciae, etc. The reactions, both passive and active, induced in such motor structures reflexly by environmental stimuli tend therefore secondarily to be followed and accompanied by reflex reactions initiated from proprioceptors.

**Conduction.**—The process by which the excitement generated in the afferent neuron travels along the reflex arc is known as conduction. Conduction along afferent and efferent nerves differs in some important respects from that obtaining in the nerve centre; *i.e.*, in the piece of the central nervous system connecting the afferent nerve with the efferent nerve. In a nerve trunk the excited state set up in it by a stimulus travels along its fibres as a wavelike disturbance, called an impulse, at a speed of about 100 m. (325 ft.) per second. An impulse does not alter in intensity or speed as it travels. A nerve trunk when excited at some point along its length transmits the impulse in both directions (*i.e.*, both up and down each fibre) from the point stimulated. This is true whether the fibre is afferent or efferent. The speed of travel of the nervous impulse along the nerve trunk is the same whether the nervous impulse is weak or intense. The nerve trunk shows practically no delay in its response to an effective, even though weak, stimulus, and its response ceases practically at once on cessation of the exciting stimulus. When excited by repeated brief stimuli the rhythm of the response corresponds closely with that of the stimuli, even when the frequency of the latter is as high as 500 per second. Finally, nerve-trunk conduction is singularly resistant to fatigue, to impoverished blood supply, and to many drugs that powerfully affect reflex actions.

Through the central nervous organ the travel of the impulse exhibits departure from these features. Its intensity is liable to be altered in transit. Its time of transit is much longer than for a similar length of nerve trunk. Its direction of transmission becomes polarized; that is, confined to one direction along the nervous path. To a strong stimulus the central reaction, instead of being as brief as an impulse, may endure for a whole second or more. A stimulus not capable of evoking a response from a centre when applied once may by simple repetition become effective (temporal summation).

It is in the gray matter that conduction differs in these respects from conduction in nerve trunks. In the gray matter each afferent fibre breaks up into branching threadlets which ramify in various directions and terminate in close apposition with other neurons. The point of nexus of one neuron with another is termed the synapse. The distance between two neurons at the synapse is about 200 Å (angstrom units; 1 Å =  $\frac{1}{10,000,000}$  mm., or about  $\frac{1}{250,000,000}$  in.). The absence of cytoplasmic continuity between the neurons is the anatomical basis that accounts for the slight delay in the speed of the impulse at the synapse and for the polarization of the direction of the impulse.

**Reflex Reactions.**—When the spinal cord is severed at any point the reflex arcs of the portion of the body behind the transection are quite cut off from the rest of the nervous system in front, including the brain. The reflex reactions elicited from the thus isolated region cannot therefore be modified by the action of the higher nervous centres. In the head the local centres are overlaid by higher centres which cannot by any simple severance be separated from them. By studying, therefore, the powers of the cord behind a complete spinal transection, information can be obtained

as to the powers of the purely local or segmental reflex mechanisms.

The so-called flexion reflex of the limb is one of the most accessible of the local reflex reactions which can thus be studied with an isolated portion of the spinal cord as its centre. Let it be supposed that the limb observed is the hind limb. The three main joints of the limb are the hip, the knee, and the ankle. Each of these joints is provided with muscles which flex (bend) it, and others which extend (straighten) it. It is found that the reflex throws into contraction the flexor muscles of each of these joints. It matters little which of all the various afferent nerves of the limb is stimulated; whichever of these the afferent nerve may be, the centrifugal discharge goes to practically the same muscles, namely, always to the flexors of the joints.

Not only does the reflex action not discharge motor impulses into the nerves of the extensor muscles, but if the spinal cord happens to be discharging impulses into these nerves when the reflex is evoked this discharge is suppressed or diminished (inhibited). In this way the latter muscles are prevented from impeding the action of the contracting flexors. This inhibition prevents other reflexes from upsetting for the time being the due action of the flexion reflex, for it renders the muscles opposing that reflex less accessible to motor discharge through the spinal cord, whatever the quarter from which incitation to that discharge may come.

A feature of this reflex is its graded intensity. A weak stimulus evokes in the flexor muscles a contraction which is weak and in the extensor muscles a relaxation which is slight. In the case of the muscle fibre, any strength of stimulus, if sufficient to excite it at all, excites the fibre totally and evokes its full contraction, and this latter remains the same in amount so long as the mechanical and nutritive conditions of the fibre remain constant. With each muscle fibre reacting on this "all-or-none" principle and each nerve fibre similarly responding (*see ALL-OR-NONE LAW*), different amounts of contraction yielded by the muscle under different strengths of stimulation of its nerve signify differences simply in the number of muscle fibres the stimulus excites. In other words the weaker stimuli excite fewer of the nerve fibres innervating the muscle.

When the tension developed by the muscle (*e.g.*, against a stiff spring) reaches the maximum obtainable from it, that fact tells us that all the muscle fibres are then in contraction; when the tension development is less than maximal, some of the muscle fibres are not in action. A stimulus to the nerve which evokes maximal tension from the muscle is one which succeeds in exciting all the nerve fibres innervating the muscle, and any stimulus which evokes less than maximal tension is leaving some of the nerve fibres idle.

The tension developed by a muscle under reflex excitation falls short of its maximal tension, even when the afferent nerve is stimulated maximally. The reflex activates a proportion only of the total aggregate of the muscle's fibres, and therefore a proportion only of the spinal motor neurons innervating the muscle. But within the range of the limit imposed by the maximal number of muscle fibres which it can activate, the grading of the number activated in accordance with the grading of the strength of stimulation of the afferent nerve is very delicate, much more so than in the case of the motor nerve itself. The actual fractional proportion of the muscle's total aggregate of motor units which an afferent nerve, maximally stimulated, can activate differs from one afferent nerve to another, and for the same afferent nerve in different experiments; *e.g.*, a subconvulsive dose of strychnine raises the size of the fraction. The threshold value of stimulus for the reflex is usually higher than for the contraction of the muscle from the motor nerve.

Spinal reflex action no more regards "muscles" than does a motor centre of the cerebral cortex. Both ignore muscles as entities and have in view movements purely. A weak flexion reflex activates a few fibres of each of the several flexor muscles of the limb. The reflex treats a complex composed from some (*i.e.*, those of similar threshold for the particular afferent nerve) motor units of hip flexor, of knee flexor, and of ankle flexor as functionally more homogeneous than is the total group of fibres composing any one of these muscles alone.

Reflex inhibition has its seat in the gray matter of the spinal centre. It acts at some point in the reflex arc upstream from the all-or-none motor unit (motor nerve fibre with its group of muscle fibres). The inhibitory reflex is, like the excitatory, capable of very delicate grading; its effect in diminishing or precluding this or that amount of an excitatory reflex is effected entirely by regulating the number of the motor units thrown out of action or kept out of action. Intensity of contraction or of relaxation is thus in both cases a question simply of number of motor units reacting. The reflex centre continues discharging impulses for a certain time after its exciting stimulus has ceased. This after-discharge succeeding a strong stimulus may persist even for several seconds.

**Refractory Phase.**—Besides characters common to all or many spinal reflexes certain spinal reflexes have features peculiar to themselves or exhibited by them in degrees not obvious in other reflexes. One of these features is refractory phase. The scratch reflex exemplifies this. In the dog, cat, and many other animals the hind limb often performs a rapid scratching movement, the foot being applied to the skin of the shoulder or neck as if to groom the hairy coat in that region. This movement is in the intact animal under control of the brain, and can be executed or desisted from at will. When certain of the higher centres in the brain have been destroyed, this scratching action occurs very readily and in an uncontrolled way. When the spinal cord has been severed in the neck this scratching movement of the hind limb can be elicited with regularity as a spinal reflex by merely rubbing the skin of the side of the neck or shoulder, or applying there a weak electric current to the skin.

In this reflex the stimulus excites afferent nerves connected with the hairs in the skin, and these convey impulses to the spinal centres in the neck or shoulder segments; these in turn discharge impulses into nerve fibres entirely intraspinal, passing backward along the cord to reach motor centres in the hind limb region. These motor centres in turn discharge centrifugal impulses into the muscles of the hind limb of the same side of the body as the shoulder that is the seat of irritation. The motor discharge is peculiar in that it causes the muscles of the hind limb to contract rhythmically at a rate of about four contractions per second, and the discharge is peculiar further in that it excites the flexor and extensor muscles of the joints alternately so that at the hip, for instance, the limb is alternately flexed and extended, each single phase of the movement lasting about an eighth of a second.

Now this rhythmic discharge remains the same in rate whether the exciting stimulus applied to the skin is continuous or one of many various rates of repetition. Evidently at some point in the reflex arc there is a mechanism that, after reacting to the impulses reaching it, remains for a certain brief part of a second unresponsive, and then becomes once more for a brief period responsive, and so on. This phasic alternation of excitability and inexcitability repeats itself throughout the continuance of the reflex. The phase of inexcitability is termed the refractory phase. Its seat lies in the spinal centre. A similar element almost certainly forms part of the coordinating mechanism for many other cyclic reflexes, including those of the stepping of the limbs, the movement of the jaw in mastication, the action of the eyelids in blinking, and perhaps the respiratory movements of the chest and larynx.

**Fatigue.**—Nerve trunks do not easily tire out under even the most prolonged stimulation. Reflex actions on the other hand relatively soon tire. Some are more resistant, however, than are others. The flexion reflex may be continued for ten minutes at a time. As a reflex tires, the muscular contraction which it causes tends to become less intense and less steady. The relatively rapid onset of fatigue in reflexes is counterbalanced by speedy recovery in repose. A long flexion reflex, when from fatigue it has become weak, tremulous, and irregular, will recommence after 30 seconds' repose with almost the same vigour and steadiness as if it had not recently been tired out.

The natural movements to which the artificially provoked reflexes seem to correspond do not demand prolonged motor activity or, when they do, demand it in rhythmic repetition with intervening pauses which allow repose.

**Reflex Postures.**—But there are certain reflexes which do per-

sist for long periods at a time. These are reflex postures. The hind limbs of the spinal frog (one in which the spinal cord has been surgically isolated from the brain) assume an attitude which is reflex, for it ceases on severance of the afferent spinal roots. This attitude is one of flexion at hip, knee, and ankle, resembling the well-known natural posture of the frog as it squats when quiet in the tank. Similarly in the decerebrate dog or cat certain muscles (*e.g.*, the limb extensors) exhibit a persistent contraction. These tonic reflexes are related to attitudes. In the dog and cat they are exhibited by those muscles whose action antagonizes gravity in postures which are usual in the animal; thus the extensors of the knee and hip and shoulder and elbow are in tonic contraction during standing. The postural contraction is accompanied by electrical "action currents" like those of other contractions, though weak and indicative of self-smothering from the rhythms being asynchronous in the contributory fibre groups. The postural contraction of the extensor muscles in the maintenance of the erect posture is traceable to a reflex, called the stretch reflex. A stretch (*e.g.*, by a pull upon the tendon) lengthening the muscle by even so little as 0.5% excites reflex contraction of some of its fibres. The passive stretch is a mechanical stimulus to some of the proprioceptive organs (perhaps the muscle spindles) in the muscle. The reflex is therefore unobtainable when the afferent nerve fibres of the muscle itself have been severed. The essential centre for the stretch reflex is spinal, but midbrain and cerebellar centres much reinforce it. In the erect posture the head, neck, tail, and jaw would droop and the limbs fold up under their own weight and that of superincumbent parts, were not the "antigravity" muscles checked from yielding by the stretch reflex which their own passive yield induces in themselves. Hence the reflexly maintained standing posture is a multiple stretch reflex. Considerable latitude of actual pose is allowed to the individual parts because each muscle involved acts for itself and develops and regulates its own stretch reflex.

Characteristic of reflex postural contraction is its continuance for long spells at a time without obvious fatigue. Attempts to reproduce this feature by electrical stimulation of afferent nerves or of the muscle's motor nerve are uniformly unsuccessful. The suggestion has therefore been made that the postural contraction of muscle is due to a different process in the muscle fibre from that of the ordinary contraction executing movements and so easily and often studied under electrical stimulation in the laboratory. A. Forbes, however, offered the satisfactory explanation that the postural contraction, while the same process as that of ordinary reflex and other contraction, involves usually relatively few motor units at a time and these, as they fatigue, are replaced by others. The stretch which is the essential stimulus is automatically shifted to fresh motor units as soon as those already in operation begin to yield and give out.

The eyeballs are eminently organs which, the gaze being a posture, employ active postures throughout the waking day. The proprioception of the neck muscles excites from the cervical spinal cord reflex influences acting on the nerves of the eyeball muscles. An instance is: turning of the neck toward one side excites turning of the eyeballs toward the opposite side. Or again, a clockwise partial rotation of the neck round its long axis excites from the neck proprioceptor a compensatory counterclockwise shifting of the eyeballs. These reflex postures of the eyeballs are sometimes called compensatory, because they tend to keep the gaze level despite displacements of the head by the movements of the neck.

When the cord or the medulla and cord of an animal (cat) is surgically isolated from the brain, the animal's composite stretch reflex enables it when placed in the erect posture to maintain that attitude, even for hours at a time; but it is incapable of assuming that posture when laid, for instance, on its side. But when the midbrain is retained in addition to hindbrain and cord, the animal has that power of righting itself. These righting reflexes are likewise postural and largely evoked by the otolith organs. Although not truly spinal reflexes, their field of nervous operation overruns into the spinal cord.

**Interaction Between Reflexes.**—At the commencement of every reflex arc is a receptive neuron extending from the receptive

surface to the central nervous organ. This neuron forms the sole avenue which impulses generated at its receptive point can use, whatever their destination may be. This neuron is therefore a path exclusive to the impulses generated at its own receptive point, and other receptive points than its own cannot employ it. A single receptive point may play reflexly upon a considerable number of different effector organs. It may be connected through its reflex path with many muscles and glands in many different regions. Yet all its reflex arcs spring from the one single shank or stem; *i.e.*, from the one afferent neuron that conducts from the receptive point at the periphery into the central nervous organ.

But at the termination of every reflex arc is found a final neuron, the ultimate conductive link to an effector organ (muscle or gland). This last link in the chain (*e.g.*, the motor neuron) differs obviously in one important respect from the first link of the chain. It does not subserve exclusively impulses generated at one single receptive source, but receives impulses from many receptive sources situated in many and various regions of the body. It is the sole path which all impulses, no matter whence they come, must travel if they are to act on the muscle fibres to which it leads.

Therefore, while the receptive neuron forms a private path exclusively serving impulses of one source only, the final or efferent neuron is, so to say, a public path common to impulses arising at any of many sources of reception. A receptive field (*e.g.*, an area of skin) is analyzable into receptive points. One and the same effector organ stands in reflex connection not only with many individual points, but even with many various receptive fields. Reflexes generated in manifold sense organs can pour their influence into one and the same muscle. Thus a limb muscle is the terminus of many reflex arcs arising in various parts of the body. Its motor nerve is a path common to all the reflex arcs which reach that muscle.

Reflex arcs show, therefore, the general features that the initial neuron of each is a private path belonging exclusively to a single receptive point (or small group of points); and that finally the arcs discharge into a path leading to an effector organ; and that their final path is common to all receptive points wherever they may lie in the body, so long as they have connection with the effector organ in question. Before finally converging upon the motor neuron the arcs converge to some degree. Their private paths join internuncial paths common in various degrees to groups of private paths. The terminal path may, to distinguish it from internuncial common paths, be called the final common path. The motor nerve to a muscle is a collection of final common paths.

Certain consequences result from this arrangement. One of these is the preclusion of essential qualitative difference between nerve impulses arising in different afferent nerves. If two conductors have a tract in common, there can hardly be essential qualitative difference between their modes of conduction.

A second consequence is that, each receptor being dependent for final communication with its effector organ upon a path not exclusively its own but common to it with certain other receptors, such nexus necessitates successive and not simultaneous use of the common path by various receptors using it to different or opposed effect.

In the simultaneous correlation of reflexes some reflexes combine harmoniously, being reactions that mutually reinforce. These may be termed allied reflexes, and the neutral arcs which they employ may be termed allied arcs. On the other hand, some reflexes, as mentioned above, are antagonistic one to another and incompatible. These do not mutually reinforce; instead, one of them inhibits the other.

**Allied Reflexes.**—What happens when trains of impulses, traveling by convergent afferent arcs, meet at the same common path? With convergent reflexes that are allied in the above sense, this case must be one of extremely frequent occurrence and the management of the interaction between the convergent streams of impulses must be a fundamental factor in nervous coordination. The afferent path A discharges into the intraspinal motor neurons of the knee flexor and can activate 75% of them. The afferent path B also discharges into the motor neurons of the same muscle

and can activate 75% of them. When the muscle is reflexly contracting to A with a tension 75% of that of the muscle's maximal contraction, stimulation of B is added. The contraction tension in result rises to 85% of the maximal. The inference is that for 65% of the total motor units of the muscle the excitation from A acts upon the same motor units as would that from B. In other words 65% of the total aggregate of the motor units of the muscle are common to A and to B. The stream of impulses arriving at these common motor units from B when A's stream is already activating them leaves their activity unchanged, failing either to increase or to diminish it. A's stream, which is engaging them, precludes B's stream from engaging them. This is termed occlusion.

The final common path under the competition of allied arcs is comparable with a telephone line already busy for one subscriber and for that time engaged and unavailable to other subscribers. The action of the principle of the final common path may be instanced in regard to allied arcs in the scratch reflex as follows. If, while the scratch reflex is being elicited from a skin point at the shoulder, a second point 1 cm. ( $\frac{1}{2}$  in.) from the first point, but also in the receptive field of skin, is stimulated, the stimulation at this second point favours the reaction from the first point. This is well seen when the stimulus at each point is of subminimal intensity. The two stimuli, though each unable separately to invoke the reflex, yet do so when applied both at the same time. The receptive field of a reflex is really the common area of commencement of a number of allied arcs.

**Antagonistic Reflexes.**—But not all reflexes connected to one and the same common final path stand to one another in the relation of allied reflexes. Suppose during the scratch reflex a stimulus is applied to the foot not of the scratching side but of the opposite side. The left leg, which is executing the scratch reflex in response to stimulation of the left shoulder skin, is cut short in its movement by the stimulation of the right foot, although the stimulus at the shoulder to provoke the scratch movement is maintained unaltered all the time. The stimulus to the right foot will temporarily interrupt a scratch reflex, or will cut it short or will delay its onset; which of these occurs depends on the time relations of the stimuli. The inhibition of the scratch reflex occurs sometimes when the contraction of the muscles innervated by the reflex conflicting with it is very slight. There is interference between the two reflexes and the one is inhibited by the other.

The reflex from the right foot evokes at the opposite (left) knee extension; in doing this it causes steady excitation of extensor neurons of that knee and steadily inhibits the flexor neurons. But the scratch reflex causes rhythmic excitation of the flexor neurons. In this conflict the flexor neurons, as a final common path, therefore lie under the influence of two antagonistic reflexes, one of which would excite them to rhythmical discharge four times a second, while the other would continually repress all discharge in them.

In all these forms of interference there is a competition, as it were, between the excitatory stimulus used for the one reflex and the excitatory stimulus for the other. Both stimuli are in progress together, and the one in taking effect precludes the other's taking effect as far as the final common path is concerned.

Again, if, while stimulation of the skin of the shoulder is evoking the scratch reflex, the skin of the hind foot of the same side is stimulated, the scratching may be arrested. Stimulation of the skin of the hind foot in a way that has the character of threatening the part with damage (nociceptive stimulus) causes the leg to be flexed, drawing the foot up by steady maintained contraction of the flexors of the ankle, knee, and hip. Here, therefore, there is an arc that discharges into a final path, common to it and to the scratch reflex arc; both these arcs employ the same effector organ, namely, the knee flexor, and employ it by the common medium of the final pathway. But though the channels for both reflexes discharge into the same final common path, the excitatory flexor effect specific to each differs strikingly in the two cases. In the scratch reflex the flexor effect is an intermittent effect; in the nociceptive flexion reflex the flexor effect is steady and maintained. The scratch reflex is set aside by that of the nociceptive arc from the

homonymous foot. (The term homonymous is used here and below to indicate a common locus or other intimate experimental relationship.)

The stimulation which previously sufficed to provoke the scratch reflex is no longer effective, though it is continued all the time. But when the stimulation of the foot is discontinued the scratch reflex returns. In that respect, although there is no enforced inactivity, there is an interference that is tantamount to, if not the same thing as, inhibition. Though there is no cessation of activity in the motor neuron, one form of activity that was being impressed upon it is cut short and another takes its place. A stimulation of the foot too weak to cause more than a minimal reflex often will suffice completely to interrupt, cut short, or prevent onset of the scratch reflex.

The kernel of the interference between the homonymous flexion reflex and the scratch reflex is that both employ the same final common pathway to different effect—just as in the interference between the crossed extension reflex and the scratch reflex. Evidently, the homonymous flexion reflex and the crossed extension reflex both use the same final common pathway. And they use it to different effect. The motor neuron to the flexor of the knee being taken as a representative of the final common path, the homonymous flexion reflex inhibits it from discharging. Hence if, while the direct flexion reflex is in progress, the crossed foot is stimulated, the reflex of the knee flexor is inhibited. The crossed extension reflex therefore inhibits not only the scratch reflex but also the homonymous flexion reflex.

Further, in all these interferences between reflexes the direction taken by the inhibition is reversible. Thus the scratch reflex is not only liable to be inhibited by, but is itself able to inhibit, either the homonymous flexion reflex or the crossed extension reflex; the homonymous flexion reflex is not only capable of being inhibited by the crossed extension reflex, but conversely in its turn can inhibit the crossed extension reflex. These interferences are therefore reversible in direction. Certain conditions determine which reflex among two or more competing ones shall obtain mastery over the final common path and thus obtain expression.

As to the intimate nature of the mechanism which thus, by summation or by interference, gives coordination where neurons converge upon a common path, it is difficult to surmise. In the central nervous system of vertebrates, afferent neurons A and B in their convergence toward and impingement upon another neuron Z, toward which they conduct, do not make any lateral connection directly with one another—at least, there is no clear evidence that they do. It seems, then, that the only structural link between A and B is neuron Z itself. Z itself should therefore be the field of coalition of A and B if they transmit allied reflexes.

**Factors Determining the Sequence.**—The formation of a common path from tributary converging afferent arcs is important because it gives a coordinate mechanism. There the dominant action of one afferent arc or of a set of allied arcs in condominium is subject to supersession by another afferent arc or set of allied arcs, and the supersession normally occurs without intercurrent confusion.

Whatever may be the nature of the physiological process occurring between the competing reflexes for dominance over the common path, the issue of their competition, namely, the determination of which one of the competing arcs shall for the time being reign over the common path, is largely conditioned by four factors. These are spinal induction, relative fatigue, relative intensity of stimulus, and the functional species of the reflex.

**Spinal Induction.**—This refers to the ability of one spinal reflex to lower the threshold of another. Induction occurs in two forms: immediate and successive. In immediate induction the stimulus that excites a reflex tends by central spread to facilitate and lower the threshold for reflexes allied to that which it particularly excites. Thus there tends to be formed a constellation of reflexes that reinforce each other, so that a reflex figure results. If the stimulus shifts, allied arcs are by the induction particularly prepared to be responsive to it or to a similar stimulus.

Immediate induction occurs only between allied reflexes. Its tendency in the competition between afferent arcs is to fortify the

reflex just established, or, if transition occurs, to favour transition to an allied reflex. Immediate induction seems to obtain with highest intensity at the outset of a reflex, or at least near its commencement.

Successive induction is in several ways the reverse of the preceding. If the crossed-extension reflex of the limb of the spinal dog (one whose spinal cord has been severed from the brain) is elicited at regular intervals, say once a minute, by an electrical stimulus of defined duration and intensity, the resulting reflex movements are repeated each time with much constancy of character, amplitude, and duration. If in one of the intervals a strong prolonged (e.g., 30 seconds) flexion reflex is reduced from the limb yielding the extensor reflex movement, the latter reflex is found intensified after the intercurrent flexion reflex. The intercalated flexion reflex lowers the threshold for the aftercoming extension reflexes, and especially increases their after-discharge. This effect may endure, progressively diminishing, through four or five minutes, as tested by the extensor reflexes at successive intervals. Now, during the flexion reflex the extensor arcs were inhibited; after the flexion reflex these arcs are in this case evidently in a phase of exalted excitability. The phenomenon presents obvious analogy to visual contrast. The exaltation aftereffect may ensue with such intensity that simple discontinuance of the stimulus maintaining one reflex is immediately followed by spontaneous appearance of the antagonistic reflex.

The so-called mark-time reflex of the spinal dog is an alternating stepping movement of the hind limbs that occurs on holding the animal up so that its limbs dangle. The reflex can be inhibited by stimulating the skin of the tail. On cessation of that stimulus the stepping movement sets in more vigorously and at a quicker rate than before. This afterincrease might be explicable in either of two ways. It might be due to the mere repose of the reflex centre, the repose so recruiting the centre as to strengthen its subsequent action. But a similar period of repose obtained by simply supporting one limb—which causes cessation of the reflex in both limbs, the stimulus being stretch of the hip flexors under gravity—is not followed by afterincrease of the reflex. Or the afterincrease might result from the inhibition being followed by a rebound to superactivity. This latter seems to be the case. The afterincrease occurs even when both hind limbs are passively lifted from below during the whole duration of the inhibitory stimulus applied to the tail. And the reflex inhibition of the knee extensor by stimulation of the central end of its own nerve is followed by marked rebound to superactivity of the extensor itself. Again, the knee jerk, after being inhibited by stimulation of the hamstring nerve, is more brisk than before the inhibition.

By virtue of this spinal contrast, therefore, the extension reflex predisposes to and may actually induce a flexion reflex, and conversely the flexion reflex predisposes to and may actually induce an extension reflex. This process is qualified to play a part in linking reflexes together in alternating sequence.

A reflex movement must generate in its progress a number of further stimuli and throw up a shower of centripetal impulses from the moving muscles and joints into the spinal cord. Squeezing of muscles and stimulation of their afferent nerves and those of joints, etc., elicit reflexes. The primary reflex movement might be expected, therefore, of itself to initiate further reflex movement, and that secondarily to initiate further still, and so on. Yet on cessation of the external stimulus to the foot in the flexion reflex, the whole reflex comes to an end, usually at once. The scratch reflex, even when violently provoked, ceases usually within two seconds of the discontinuance of the external stimulus that provoked it. There is as yet no satisfactory explanation of this.

*Relative Fatigue.*—Another condition influencing the issue of competition between reflexes of different sources for possession of one and the same final common path is fatigue. A spinal reflex under continuous excitation or frequent repetition becomes weaker, and may cease altogether. This decline is progressive, and takes place earlier in some kinds of reflexes than it does in others. In the spinal dog the scratch reflex under ordinary circumstances tires much more rapidly than does the flexion reflex.

A reflex as it tires shows other changes besides decline in ampli-

tude of contraction. Thus in the flexion reflex, the original steadiness of the contraction decreases; it becomes tremulous, and the tremor becomes progressively more marked and more irregular. Finally, an irregular phasic tremor of the muscles is all that remains. It is not the flexor muscles themselves which tire out, for these, when under fatigue of the flexion reflex, contract no longer for that reflex but do contract in response to the scratch reflex which also employs them.

Similar results are furnished by the scratch reflex, with certain differences in accord with the peculiar character of its individual charge. One of these latter is the feature that the individual beats of the scratch reflex usually become slower and follow each other at slower frequency. Also the beats, instead of remaining fairly regular in amplitude and frequency, tend to succeed in somewhat regular groups. The beats may disappear altogether for a short time, and then for a short time reappear.

When the scratch reflex elicited from a spot of skin is fatigued, the fatigue holds for that spot, but does not implicate the reflex as obtained from the surrounding skin. The reflex is, when tired out to stimuli at that spot, easily obtainable by stimulation 2 cm. ( $\frac{1}{2}$  in.) or more away.

Recovery from the local fatigue of a spinal reflex seems to occur with remarkable speed. A few seconds' remission of the stimulus suffices for marked though incomplete restoration of the reaction. Fatigue seems a process elaborated and preserved in the selective evolution of the neural machinery. One obvious use attaching to it is the prevention of the too-prolonged continuous use of a common path by any one receptor. It precludes one receptor from occupying for long periods an effector organ to the exclusion of all other receptors. It prevents long continuous possession of a common path by any one reflex of considerable intensity. It favours the receptors taking turnabout. It helps to ensure serial variety of reaction. The organism, to be successful in a million-sided environment, must in its reaction be many sided. Were it not for such so-called fatigue, an organism might, in regard to its receptivity, develop an eye, or an ear, or a mouth, or a hand or leg, but it would hardly develop the marvelous congeries of all those various sense organs which it is actually found to possess.

The final efferent-root neuron forms the instrument for many different reflex arcs and acts. It is responsive to them in various rhythms and in various grades of intensity. In accordance with this, it seems from experimental evidence to be relatively indefatigable.

*Relative Intensity of Stimulus.*—In the transition from one reflex to another a final common path changes hands and passes from one master to another. A fresh set of afferent arcs becomes dominant on the supersession of one reflex by the next. Of all the conditions determining which one of competing reflexes shall for the time being reign over a final common path, the intensity of reaction of the afferent arc itself relatively to that of its rivals is probably the most powerful. Other things being equal, an afferent arc that strongly stimulates is more likely to capture the common path than is one excited feebly. A stimulus can establish its reflex and inhibit an opposed one only if it has intensity. This explains why, in order to produce examples of spinal inhibition, recourse has so frequently been made in past times to strong stimuli. A strong stimulus will inhibit a reflex in progress although a weak one will fail. Thus in inhibition of micturition in the spinal dog a forcible squeeze of the tail will do it, but not a weak squeeze. So, likewise, any condition that raises the excitability and responsiveness of a nervous arc will give it power to inhibit other reflexes, just as it would if it were excited by a strong stimulus.

Crossed reflexes are usually less easy to provoke, less reliable of obtainment, and less intense than are direct reflexes. Consequently, crossed reflexes usually are more easily inhibited and replaced by direct reflexes than are the latter by the former. Thus the crossed stepping reflex is easily replaced by the scratch reflex, though its stimulus may be continued all the time and though the scratch reflex itself is not a very potent reflex. But the reverse can occur with suitably adjusted intensity of stimuli.

Again, the flexion reflex of the dog's leg, when fully developed,

is accompanied by extension in the opposite leg. This crossed extensor movement, though often very vigorous, may be considered as an accessory and weaker part of the whole reflex, of which the prominent part is flexion of the homonymous limb. When the flexion reflex is poorly elicitable—as, for instance, in spinal shock or under fatigue or weak excitation—the crossed extension does not appear. But, where the flexion reflex is well developed, if not merely one foot but both are stimulated simultaneously with stimuli of fairly equal intensity, steady flexion at knee, hip, and ankle results in both limbs, and extension occurs in neither limb. The part of each reflex that affects the opposite side is inhibited by the flexion on its own side. In other words, the more intense part of each reflex obtains possession of the final common paths at the expense of the less intense portion of the reflex. But if the intensity of the stimuli applied to the right and left feet is not balanced closely enough, the crossed extension of the reflex excited by the stronger stimulus is found to exclude even the homonymous flexion that the weaker stimulus should and would otherwise evoke from the leg to which it is applied.

It was pointed out above that in a number of cases the transference of control of the final common pathway from one afferent arc to another is reversible. Other things being equal, the direction of the transference can be easily governed by making the stimulation of this receptor or that receptor the more intense. A factor largely determining whether a reflex will succeed another or not is therefore intensity of stimulus.

*Functional Species of Reflex.*—The fourth main determinant for the issue of the conflict between rival reflexes is the functional species of the reflexes. Reflexes initiated from a species of receptor apparatus that may be termed nociceptive appear to dominate particularly the majority of the final common paths issuing from the spinal cord. In the simpler sensations experienced from various kinds of stimuli applied to the skin there can be distinguished those of touch, of cold, of warmth, and of pain. The pain (nociceptive) ending may be regarded as adapted to a whole group of excitants which have, in relation to the organism, one feature in common, a noxious (injurious) character.

Considering the organism's liability to various kinds of mechanical and other damage, in a world beset with dangers amid which the individual and species have to win their way in the struggle for existence, noxious stimuli may be regarded as part of a normal state of affairs. The skin has evolved a specific sense of its own injuries. As psychical adjunct to the reactions of that apparatus, a strong displeasurable effective quality is found in the sensations they evoke. This may be a means for branding upon memory, of however rudimentary a kind, a feeling from past events that have been perilously critical for the existence of the individuals of the species. In other words, if it is admitted that damage to such an exposed sentient organ as the skin must in the evolutionary history of animal life have been sufficiently frequent in relation to its importance, then the existence of a specific set of nerves for skin pain seems to offer no genetic difficulty, any more than does the clotting of blood or innate immunity to certain diseases. That these nerve endings constitute a distinct species is argued by their all evoking not only the same species of sensation, but the same species of reflex movement as regards purpose, intensity, resistance to shock, etc. And their evolution may well have been unaccompanied by evolution of any specialized end organ, since the naked free nerve endings would better suit the wide and peculiar range of stimuli to which reaction is in this case required. A low threshold was not required because the stimuli were all intense, intensity constituting their harmfulness; but response to a wide range of stimuli of different kinds was required, because harm might come in various forms. That responsive range is supplied by the naked nerve itself, and would be cramped by the specialization of an end organ. Hence these nerve endings remained free.

In the spinal animal—where pain is of course nonexistent—the prepotent (dominant) reflexes are excited by stimulation of areas in which pain can be excited most intensely in intact animals, and likewise by stimuli that are most fitted to excite pain in intact animals. The nervous arcs of pain nerves, broadly speaking, dominate the spinal centres in peculiar degree. Pain is thus the

psychical adjunct of an imperative protective reflex. It is preferable, however, to avoid the term pain nerves, since into the merely spinal and reflex aspect of the reaction of these nerves no sensation of any kind can be shown to enter. Remembering that the feature common to all this group of stimuli is that they threaten or actually commit damage to the tissue to which they are applied, a convenient term for application to them is noxious. In that case what from the point of view of sense are cutaneous pain nerves are from the point of view of reflex action conveniently termed nociceptive nerves.

In the competition between reflexes the nociceptive as a rule dominate with peculiar certainty and facility. This explains why such stimuli have been so much used to evoke reflexes in the spinal frog, and why, judging from them, such importance for the fate of the organism belongs to spinal reflexes.

One and the same skin surface will evoke in the hind limb of the spinal dog one or other of two diametrically different reflexes depending on whether the mechanical stimulus is a harmful or a harmless touch. A needle prick to the sole of the foot causes invariably the drawing up of the limb: the flexion reflex. A harmless smooth contact, on the other hand, causes extension: the extensor thrust described above. This flexion is therefore a nociceptive reflex. But the scratch reflex—which is so readily evoked by simple light irritation of the skin of the shoulder—is relatively mildly nociceptive. When the scratch reflex and the flexion reflex are in competition for the final neuron common to them, the flexion reflex more easily dispossesses the scratch reflex from the final neuron than does the scratch reflex the flexion reflex. If both reflexes are fresh, and the stimuli used are such that, when employed separately, they evoke their respective reflexes with some intensity, it is the flexion reflex that is usually prepotent. Yet if a strong stimulus suitable for producing the scratch reflex is applied while the flexion reflex is being moderately evoked, the steady flexion is replaced by the rhythmic scratch reflex, and this occurs even though the stimulus for the flexion reflex is maintained unaltered. When the stimulus producing the scratch reflex is discontinued the flexion reflex reappears as before.

In a decerebrate animal, where a tonic reflex (one that relaxes only very gradually) is maintaining contraction in the extensor muscles of the knee, stimulation of the nociceptive arcs of the limb easily breaks down that reflex; *i.e.*, the nociceptive reflex dominates the motor neuron previously held in activity by the postural reflex. And nociceptive reflexes are relatively little depressed by spinal shock.

Besides those receptors that react to direct noxious stimuli the skin has others concerned with functions of vital importance to the species and bound up with sensations of similarly intense affective quality; *e.g.*, those concerned with sexual functions. In the male frog the sexual clasp is a spinal reflex. The cord may be divided both in front and behind the brachial (forelimb) region without interrupting the reflex. Experiment shows that from the spinal male at the breeding season, and also at other times, this reflex is elicited by any object that stimulates the skin of the breast. In the intact animal, on the contrary, objects other than the female are, when applied to that region, at once rejected, even though they be wrapped in the fresh skin of the female frog and in other ways made to resemble the female.

It would seem to be a general rule that reflexes arising in species of receptors which, considered as sense organs, provoke strongly affective sensation prevail (other things being equal) over reflexes of other species when in competition with them for the use of the final common path.

Of all reflexes it is those of ordinary posture that are the most easily interrupted by other reflexes. Even a weak stimulation of the nociceptive arcs arising in the foot often suffices to lower or abolish the knee jerk or the reflex extensor tonus (continuous contraction) of the elbow or knee. If various species of reflex are arranged, therefore, in their order of potency in regard to power to interrupt one another, the reflexes initiated in receptors which, considered as sense organs, excite sensations of strong affective quality are found to lie at the upper end of the scale, and the reflexes that are answerable for the postural tonus of skeletal

muscles lie at the lower end of the scale.

One great function of the tonic reflexes is to maintain habitual attitudes and postures. They form, therefore, a nervous background of active equilibrium. It is obviously advantageous that this equilibrium should be easily upset, so that the animal may respond agilely to the passing events.

**Results.**—Intensity of stimulation, fatigue and freshness, spinal induction, functional species of reflex—all these physiological factors influence the result of the interaction of reflex arcs at a common path. All resolve themselves ultimately into intensity of reaction. Thus intensity of stimulus means, as a rule, intensity of reaction. Those species of reflex which are habitually prepotent in interaction with others are those which are habitually intense, and those specially impotent in competition are those habitually feeble; e.g., the tonic reflexes of skeletal muscle. The tonic reflexes of attitude are thus easily interfered with and temporarily suppressed by intercurrent reflexes (those set up by passing events), which have the higher intensity.

The high variability of reflex reactions from one experiment or observation to another is often attributed to general conditions of nutrition, local blood supply, etc. However, variability seems far more often due to changes produced in the central nervous organ by its own functional conductive activity apart from fatigue. This activity itself causes from moment to moment the temporary opening of some connections and the closure of others. The chains of neurons, the conductive lines, have been richly revealed by the microscope. Anatomical tracing of nerve fibres may be likened to tracing the distribution of blood vessels after Harvey's discovery had given them meaning, but before the vasomotor mechanism was discovered. (The blood vessels of an organ may be turgid at one time, constricted almost to obliteration at another.) With the conductive network of the nervous system the temporal variations are even greater, for they extend to absolute withdrawal of nervous influence. Under reflex inhibition a skeletal muscle is relaxed to its postmortem length; i.e., there may then be no longer evidence of even a tonic influence on it by its motor neuron.

The final common path is handed from some group of a plus class of afferent arcs to some group of a minus class or of a rhythmic class, and then back once more to one of the previous groups, and so on. The conductive web changes its functional pattern to and fro within certain limits. It changes its pattern at the entrances to common paths. The changes in its pattern occur there in virtue of interaction between rival reflexes: occlusion, substitution by equivalence, inhibition, immediate induction, successive induction, and fatigue are factors. A new stimulus striking the receptive surfaces causes in the central organ a shift of functional pattern of the linkage. The central organ is a vast network whose lines of conduction follow a certain scheme or pattern, but within that pattern the details of connection are, at the entrance to each common path, mutable. The gray matter may be compared with a telephone exchange, where, from moment to moment, though the end points of the system are fixed, the connections between starting points and terminal points are changed to suit passing requirements. To comprehend the exchange at work, one must add to its purely spatial plan the temporal datum that within certain limits the connections of the lines shift to and fro from minute to minute. An example is the reciprocal innervation of antagonistic muscles: when one muscle of the antagonistic pair is thrown into action, the other is thrown out of action.

Reciprocal innervation is a widespread case of the general rule that antagonistic reflexes interfere where they discharge into the same final common paths. And that rule is part of the general principle of the mutual interaction of reflexes that impinge upon the same common path: unlike reflexes have successive but not simultaneous use of the common path; like reflexes mutually reinforce each other on their common path. The principle may be expressed teleologically: the common path, although economically subservient for many and various purposes, is adapted to serve but one purpose at a time; hence it is a coordinating mechanism and prevents confusion by restricting the use of the organ, its minister, to but one action at a time.

In the case of simple antagonistic muscles, and in the instances

of simple spinal reflexes, the shifts of conductive pattern due to interaction at the mouths of common paths are of but small extent. The coordination covers, for instance, one limb or a pair of limbs. But the same principle extended to the reaction of the great arcs arising in the proficient receptor organs of the head, e.g., the eye, which deal with wide tracts of musculature as a whole, operates with more multiplex shift and wider ambit. Releasing forces acting on the brain from moment to moment shut out from activity whole regions of the nervous system, as they conversely call vast other regions into play. The resultant singleness of action from moment to moment is a keystone in the construction of the individual, whose unity it is the specific office of the nervous system to perfect. The interference of unlike reflexes and the alliance of like reflexes in their action upon their common paths seem to lie at the very root of the great psychical process of attention.

The spinal cord not only accommodates reflexes centring wholly within the cord itself; it also supplies conducting paths for nervous reactions initiated by impulses derived from afferent spinal nerves, but involving mechanisms situated altogether headward of the cord, in the brain. Many of these reactions affect consciousness, occasioning sensations of various kinds.

Besides the paths followed by headward-running impulses, the spinal cord contains paths for impulses passing along it backward from the brain. These paths lie in the lateral and ventrolateral columns of the cord. The fibres of which they are composed cross but little in the cord. Their sources are various; some of them come from the hindbrain and some from the midbrain, and in the higher mammalia, especially in man and in the anthropoid apes, a large tract of fibres in the lateral column (the crossed pyramidal tract) comes from the cortex of the neopallium of the forebrain. This last tract is the main medium by which impulses initiated by electrical stimulation of the motor cortex reach the motor neurons of the cord and through them influence the activity of the skeletal muscles.

Of the function of the other tracts descending from the brain into the cord little is known except that mediate or immediately they excite or inhibit the spinal motor neurons by various levels. How they harmonize one with another in their action or what their purpose in normal life may be is at present little more than conjecture. Such terms, therefore, as "paths for volition," etc., are too schematic in their bases to warrant their discussion here.

**SPINAL CORD, DISEASES OF:** see NERVOUS SYSTEM, DISEASES OF.

**SPINE, DISEASES AND DISABILITIES OF.** The spine can be affected by more than 60 different conditions. The commonest are birth malformations, acquired growth deformities, sprains, fractures and dislocations from injuries, infections, arthritis, herniation of the intervertebral discs and cancer. All may produce pain, limited back movement, muscle spasm and deformity. The pain may radiate into the arms and legs when nerves are irritated. Prolonged pressure may cause paralysis of an extremity. The diagnosis of a given condition is established by suitable examination and laboratory survey, including X rays.

**Backache.**—The usual seat of backache is the lumbar or lumbosacral region (between or just above the hips). Chronic backache may reflect a structural inadequacy or disease.

**Lumbago.**—This condition, marked by acute pain in the lower back, is caused by a sprain: overstretching of tissues, hemorrhage into muscles and tearing of ligaments. Lumbago commonly results from lifting efforts, unexpected jarring, sudden twisting movements or a blow to the spine. Treatment includes bed rest, application of heat and massage with local analgesics.

**"Whiplash" Injury.**—The "whiplash" injury to the neck, received in automobile accidents when the occupant's head is thrown backward and then forward, is actually a sprain, characterized by pain, muscle spasm and limited motion. Treatment consists of sedation, protective support for neck or back and, occasionally, weights attached to the head or legs to stretch the injured tissues and relieve pressure on nerves. Recovery occurs in several weeks but may be prolonged.

**Arthritis.**—Rheumatoid arthritis affects spines of young adults, producing progressive destructive changes in small joints leading to fusion and permanent stiffening. In other cases, the large ligaments about the vertebrae ossify and transform the spine into one piece. Pain is outstanding and is minimized by braces, X-ray therapy and cortisone. Symptoms disappear as the spine becomes rigid and the process inactive.

Degenerative arthritis is manifested by narrowing of disc spaces, sclerosis of adjacent vertebrae and formation of spurs at their margins. Other cases show changes in the facets and the joints become painful. Mild symptoms are alleviated by braces and corsets. Severe pain may necessitate bed rest, leg traction and physical therapy, followed with a back support. (See ARTHRITIS.)

**Infection.**—Infections producing pus in the spine are rare, but when present cause severe symptoms. The patient is usually acutely ill. Isolation of the offending bacteria and utilization of the specific antibiotic drug, together with good nursing care, is essential. Drainage of abscesses facilitates recovery.

Chronic infections, such as tuberculosis, may produce destruction of the vertebrae and adjacent discs. Pus and destroyed tissue accumulate in front of and behind the vertebrae. Pressure on the spinal cord may result in paralysis of the body below the level of infection. Treatment with modern drugs, supplemented by surgery in which the involved segment of the back is made solid, hastens recovery.

**Disc Disorders.**—The intervertebral discs serve as shock absorbers between adjacent vertebrae. The rubbery central nucleus sometimes undergoes degeneration and allows the contiguous vertebrae to rub on each other. The resultant arthritis produces local pain or radiating pain down an extremity. The nucleus, in other cases, escapes through the back wall of the disc causing spinal cord pressure. This is a protruded or herniated disc, and causes neuritic arm or leg pain, depending upon the location of the spinal lesion.

Treatment consists of traction, supports and physical therapy during the initial attack or in mild recurrent episodes. Severe, unremitting pain necessitates surgery to remove extruded nuclear material and relieve pressure on nerves. Spinal fusion is often performed simultaneously to prevent further collapse of the disc and subsequent pain.

**Cancer.**—Cancer arises in the spine from cells that normally produce bone and cartilage, from cells in the bone marrow and from covering elements of the vertebrae. The diagnosis is established by characteristic X-ray changes and from tissue obtained by needle biopsy or surgery. Cancer originating from the thyroid gland, gastrointestinal tract, kidneys and prostate gland has a tendency to spread to the spine. The prognosis is poor, but symptomatic treatment minimizes suffering.

Noncancerous growths of the spine, on the other hand, carry a good prognosis.

**SPINEL**, a group of minerals, the typical member of which is a magnesium aluminate, to which the name was originally restricted. The group includes chromite, franklinite and magnetite, important ores of chromium, zinc and iron, respectively. The magnesia spinel, sometimes known as ruby spinel, is one of the 16 minerals that have achieved importance as a gem, both natural and synthetic (see GEM: Synthetic Gems). The name is from the French *spinelle*, derived from the Latin *spina* ("thorn"), perhaps in allusion to the sharp, needlelike angles of the crystals. Spinel has the general composition  $R''O \cdot R_2'''O_3$ , where  $R'' = \text{Mg, Fe, Mn, Zn}$ , and  $R''' = \text{Al, Fe}''', \text{Cr}'''$ .

All spinels crystallize in the cubic system, typically in octahedra. Twinning is common, the octahedral face being the

twin plane, giving a characteristic form known as the spinel twin.

The group of spinel minerals includes the following members:

Magnesia spinel . . .	$\text{MgAl}_2\text{O}_4$	Magnesioferrite . . .	$\text{MgFe}_2\text{O}_4$
Pleonaste . . .	$(\text{Mg, Fe})\text{Al}_2\text{O}_4$	Magnetite . . .	$\text{FeFe}_2\text{O}_4$
Hercynite . . .	$\text{FeAl}_2\text{O}_4$	Gahnite . . .	$\text{ZnAl}_2\text{O}_4$
Picotite . . .	$(\text{Mg, Fe})(\text{Al, Cr})_2\text{O}_4$	Franklinite . . .	$(\text{Zn, Mn})\text{Fe}_2\text{O}_4$
Chromite . . .	$\text{FeCr}_2\text{O}_4$		

Cleavage is typically absent in these minerals with the exception of the zinc spinel (cleavage on 111), but an octahedral parting is observable in magnetite and franklinite. The hardness is variable; in ordinary spinel it is 7.5–8, the gem varieties being 8, but magnetite is 6 and chromite is 5.5. The specific gravity varies with the composition, from 3.6 (magnesia spinel) to 5.2 (magnetite). The light refraction shows a range from 1.718 (pure magnesia spinel), hercynite 1.80, to picotite 2.05, chromite 2.10 and magnetite 2.42.

Spinel varies much in colour. Natural magnesia spinels are pink, red and blue. The pure magnesia spinel is colourless, hercynite is dark green in thin slices and picotite and chromite are brown in the thinnest sections. Spinel is readily produced in all colours artificially. Magnesia spinel melts at  $2,135^\circ \text{C}$ . and between this compound and  $\text{FeAl}_2\text{O}_4$  (hercynite) there is complete miscibility as revealed in spinel analyses, but solid solution between  $(\text{Mg, Fe})\text{Al}_2\text{O}_4$  (pleonaste) and magnetite is very limited. The natural spinels which are used in jewelry are found mostly in gem gravels, the chief localities being Ceylon, Thailand (Siam) and upper Burma.

Spinel occurs both in igneous and metamorphic rocks. The home of the magnesia spinel is in thermally altered dolomites where it arises by reaction of alumina with dolomite. There it is usually accompanied by calcite and forsterite. The iron-rich member of the group, pleonaste, is common both in ultrabasic rocks such as dunites and in quartzless argillaceous hornfelses and gneisses. In these latter it is almost universally accompanied by cordierite and frequently by sillimanite, andalusite or corundum. Hercynite is characteristic of the granulites of Saxony in association with garnet, sillimanite, etc.

The chromiferous spinel, picotite, is relegated to the ultrabasic rocks, as dunite, hercynite and the serpentines derived from them. Gahnite, the zinc spinel, occurs in schists associated with zinc ores and in pegmatites in Finland and at Broken Hill, New South Wales, Austr., while franklinite is associated with zinc and manganese minerals in limestone at Franklin Furnace, N.J.

**SPINELLO ARETINO** (LUCA SPINELLO) (c. 1346–1410), prolific late Gothic Italian painter, was born at Arezzo in or soon after 1346. Trained in a local workshop, he seems rapidly to have come under the influence of Orcagna and Nardo di Cione, whose style is reflected in his first major work, a fresco cycle in S. Francesco at Arezzo. A facile artist, Spinello's reputation soon spread beyond his native town. In 1384–85 he painted a polyptych for Monteliveto Maggiore (panels in the Pinacoteca at Siena, the Fogg museum at Cambridge, Mass., and Budapest), and about 1387 executed a fresco cycle in the small church at Antella, near Florence. A cycle of scenes from the life of St. Benedict in the sacristy of S. Miniato al Monte, Florence, dates from the same time.

To the year 1391 belongs a triptych commissioned for S. Andrea at Lucca, now in the Accademia, Florence, which was painted in conjunction with Lorenzo di Niccolò. In the same year he began work on some frescoes in the Campo Santo at Pisa. Further commissions at Arezzo followed, and between 1404 and his death on March 14, 1410, he seems to have divided his time between Arezzo and Siena, where he undertook work for the cathedral (lost) and executed (1407–10) a cycle of fresco scenes from the life of Pope Alexander III in the Sala di Balia of the Palazzo Pubblico. These and the Pisa frescoes constitute his most important works. Spinello was at best a minor artist with a vigorous sense of narrative, and his interest is due in the main to the transitional character of his late style, which anticipates the realistic painting of the early 15th century. (J. W. P. H.)

**SPINET**, a small, compact form of the harpsichord. It is wing shaped, with only one set of strings placed at an oblique angle to the keyboard. The spinet appeared about 1660 and became popular as a substitute for the larger harpsichord, suitable for small rooms. Large numbers were made during the late 17th and 18th centuries, particularly in England. See **HARPSICHORD**.

(G. F. OL.)

**SPINNING** is the forming of continuous thread by twisting together several overlapping fibres or filaments. (The word also refers to the extrusion of viscous materials to form long filaments of chemical origin; see **FIBRE**.) Two or more of the spun threads may again be twisted together to obtain a stronger thread or cord. These continuous threads are necessary for the production of woven fabrics and also as cordage and rope for various purposes. Before the fibre is spun it is cleaned and straightened; preliminary processes include carding and, for the finer yarns, combing (*q.v.*).

The first spinning no doubt consisted of twisting a few fibres together with the fingers to make short cords for fastenings or bindings. When longer threads were made, the finished length was wound onto a stick, and this in time developed into the spindle, the first spinning tool. An improvement took place by adding to the end of the stick a blob of clay or a round piece of wood, known as the "whorl," which enabled the stick (hanging free, vertically) to continue to twist for a time and thus to insert the turns of twist into the thread. The size and weight of the stick and whorl varied with the fineness of the yarn that was to be produced, and very fine yarns were spun by suitable choice of these weights. For thousands of years this simple device remained the only means of spinning fibres into thread. Three basic motions were performed in rotation: the fibres were drawn out, then they were twisted together, and finally the finished length of thread was wound onto the spindle. A useful but not essential accessory was the distaff, a stick, sometimes straight and sometimes forked or carved, to which the fibres were bound in a position from which they could be drawn out to the required degree of fineness. The distaff was held in the left hand or under the spinner's arm.

The first stage in the mechanization of spinning was to mount the spindle horizontally in bearings and to rotate it by a cord encircling a large hand-driven wheel. The distaff, with the fibrous material, was held in the left hand and the wheel was turned with the right hand. At the start a few turns of yarn were wound on the spindle and attached to the raw material. By drawing the raw material at an angle to the line of the spindle while it was being rotated, the thread was attenuated to the desired fineness and twist was inserted at the same time. (The thread attached to the spindle slipped over the end of the spindle and was held in place by a groove or notch.) As the twist ran more readily into the thin places in the yarn it bound up the fibres in these places so much that they resisted further attenuation, and subsequent stretching made only the thick places finer. This differential attenuation made for greater regularity in the yarn and was a great advance over the earlier method of spinning by which all the attenuation was carried out between the two hands, only twist being inserted by the twirling stick. When the length of yarn became too great for convenience, the spindle rotation was reversed and the yarn was wound on the spindle, leaving a few inches still attached to the loose material, so that another length could be spun.

This system was used in India in very early times, but was not introduced into Europe until the 14th century. It continued to be used in Europe for spinning cotton and wool until the beginning of the 19th century, and in America it survived in isolated districts until the end of the century.

The next stage of development was the Saxony wheel, introduced in Europe at the beginning of the 16th century. It incorporated a bobbin within a flyer and was an important development, for whereas the earlier spindle method was an intermittent one, first producing a length of yarn and then winding it on a stick, the Saxony wheel produced yarn and wound it on the bobbin continuously. The distaff was in this case a stationary vertical rod. Attenuation of the mass took place between the spinner's hands; the flyer, driven from the large wheel actuated by a foot treadle,

BY COURTESY OF THE NEW YORK STATE HISTORICAL ASSOCIATION, COOPERSTOWN  
EARLY AMERICAN FOOT-PEDAL SPINNING WHEEL

inserted the twist; and the twisted yarn then passed onto the bobbin. This method could be used only for coarse-yarn production from wool or cotton; fine yarns, which were too weak to be wound onto a bobbin in this way, continued to be made by the method described above. These two systems are the basis of all modern spinning machinery.

In the 18th century a number of developments led to the rapid industrialization of all textile manufacture (see **INDUSTRIAL REVOLUTION: Textile Industry**). Spinning was up to this time a household enterprise, done mostly by women (hence "spinsters," in modern usage applied to all unmarried women, and "distaff" as used for woman's domain in general); three to five spinners were required to supply one loom. John Kay's invention of the flying shuttle, which greatly increased the output of the loom, led to a shortage of yarn which in turn stimulated the search for faster spinning methods, and three different machines were invented in the space of a few years.

The first was the spinning jenny, invented about 1764 by James Hargreaves (patented 1770). This machine was virtually derived from the spinning stick method, having the same basic action in that cotton material was attenuated, twisted, and then wound on a spindle before another length was spun. It had a number of spindles side by side, operable by one person, and therefore the output per operative was increased markedly. The yarn produced was very full, and was suitable only for the coarser cloths. (This type of spinning machine is still in use in some coarse-yarn mills operating on both cotton and wool.)

The second machine was that of Richard Arkwright, invented about 1767 (patented 1769). It incorporated attenuating or drafting rollers, which had been invented independently in 1738 by Lewis Paul, followed by the spindle and bobbin arrangement of the Saxony wheel, so that yarns could be produced continuously. Again, many spindles could be built into one machine, and could be looked after by a single operator. The yarn made on this machine was stronger than that from Hargreaves' jenny, and was more suitable for the longitudinal threads, or warp, in weaving.

The third machine, which became known as the "mule," was invented by Samuel Crompton about 1779, and was more successful than either of the other two. It made use of Paul's drafting rollers for attenuation and spindles similar to those of the spinning stick, but there were numerous spindles side by side on one machine (over 1,000 in many instances) and operative productivity was high. It could spin any type of yarn, from the finest to very coarse. For well over a century this was the principal spinning machine in English factories.

Concurrently, the preparatory processes were also being mechanized. After the opening and cleaning processes, the fibres must be separated from one another by a "carding" process, originally done by hand and eventually by machine. Following the carding, the fibres in the slivers (rope-like strands delivered by the cards) must be made parallel; this was a function of Paul's draw frame, which was improved by Arkwright later in the century. The slivers had next to be made finer, by a speed frame process, first attenuating the draw frame slivers by passing them through drafting rollers, then twisting them slightly by flyers, and finally winding them onto bobbins. Two or three successive speed frame processes were commonly used to make the slivers fine enough for spinning; these fine slivers were called rovings. All these preparatory machines were bulky and heavy, and because special buildings were needed to accommodate them, they accelerated the establishment of the factory system.

The next significant development was the introduction of two

other spinning machines, both invented in the United States about 1828. One was the cap spinning machine of Charles Danforth, and the other the ring spinning machine invented by John Thorp. Both had attenuating systems similar to the Paul mechanism; and while the Danforth machine had a steel cap on the spindle in place of the usual flyer, the edge of the cap guiding the yarn onto the driven bobbin enclosed by the cap, the Thorp machine had a steel ring surrounding the spindle and bobbin, and on a flange of the steel ring was clipped a steel C-shaped "traveler" through which the yarn passed on its way to the bobbin; the traveler revolved on the ring to insert twist into the yarn. Both these machines were immediately popular in the U.S. and eventually found their way into English mills. The Danforth machine was fairly popular in woolen mills, and is still used to a limited extent. The Thorp machine was not widely adopted in English cotton mills for some time, but it has now almost entirely replaced the mule on account of its greater productivity and simplicity.

Mule spinning was done almost entirely by men, but the Danforth and Thorp machines, which were simpler in operation, were looked after by women, who still constitute the majority of employees in spinning mills. At one time it was customary to work only one shift, but modern practice is to run the mills for two or three shifts daily; this practice, together with a great increase in the speed of the spindle on modern machines, has led to a considerable reduction in the number of operating mills.

**SPINOLA, AMBROGIO DI**, 1ST MARQUÉS DE LOS BALBACES (1569–1630), Italian soldier whose campaigns in the Netherlands in the service of Spain made him one of the outstanding generals of his time, was born at Genoa of a family of great antiquity, wealth, and power. At that time the Genoa Republic was politically a satellite of Spain. To advance the fortunes of his house, Spinola entered into a contract with the Spanish government for service in Flanders and in 1602 marched there with a force of 9,000 men raised at his own expense. On Sept. 29, 1603, he took over command of the siege of Ostend, and his capture of the city on Sept. 22, 1604, won him a high reputation. He then visited the Spanish court at Valladolid and was appointed commander in chief in Flanders, awarded the Order of the Golden Fleece, and appointed superintendent of the *hacienda* (exchequer). The war between Spain and the Dutch in the Netherlands consisted almost wholly of sieges, and Spinola became renowned for the number of towns he took in spite of the efforts of Maurice of Nassau to defend them. On Spinola's second visit to Spain in 1606 he pledged the fortune of his house to secure funds to continue the war in Flanders. He retained his command after the Twelve Years' Truce was signed in 1609.

On the outbreak of the Thirty Years' War in 1618 Spinola conducted a vigorous campaign in the Lower Palatinate and was made captain general. Following the renewal of the Dutch war in 1621, he gained his most famous victory by the capture of Breda after a long siege (Aug. 28, 1624–June 5, 1625). This success was the subject of Velázquez's great painting, the "Surrender of Breda." Breda was the culmination of Spinola's career, for lack of funds and the enmity of Philip IV's favourite, the conde-duque de Olivares, aggravated after Spinola's third visit to Spain in 1628, paralyzed his efforts. He went to Italy in September 1629 as plenipotentiary and general in the war over the succession to the duchy of Mantua (1628–31) but died at Castelnuovo Scivina on Sept. 25, 1630, after having captured the town of Casale Monferato.

See A. Rodríguez Villa, *Ambrosio Spinola* (1904). (J. RE.)

**SPINOZA, BENEDICTUS DE** (1632–1677), author of one of the greatest metaphysical systems in the history of philosophy, was born of Jewish parents in Amsterdam, Holland, on Nov. 24, 1632. The family surname occurs in various forms: Espinoza, d'Espinoza, Despinoza, de Spinoza and simply Spinoza. The philosopher's Hebrew name was Baruch (meaning "blessed"), which, in accordance with the custom of the time, was rendered into its Latin equivalent, Benedictus.

Spinoza's grandfather and father were Portuguese crypto-Jews

(that is, descendants of Jews whom the Spanish Inquisition had compelled to embrace Christianity but who remained Jews at heart) who, with many others of their persuasion, had sought refuge in Holland after the successful revolt of the Netherlands against Spain and the granting of religious freedom by the union of Utrecht. His mother, who also came from Portugal, died in 1638, when Spinoza was barely six years old.

The Spinozas were prosperous merchants and respected members of the Jewish community in Amsterdam, and it may be assumed that Spinoza attended the school for Jewish boys founded there about 1638. The curriculum of this school comprised all the Hebrew subjects: the Old Testament, the Talmud, the Hebrew codes and the works of Ibn Ezra, Maimonides, Crescas and others. Outside school hours the boys had private lessons in secular subjects. Spinoza naturally learned Portuguese and Spanish from his parents and Dutch from his environment (Spanish was also the language of the Jewish school); he was taught Latin by a German scholar, Jeremiah Feibinger, who may also have taught him German; and he also knew some French and Italian. When he learned mathematics and physics is not known, but there were plenty of Hebrew books dealing with these sciences, and the Jewish school had a good lending library.

In March 1654 Spinoza's father died. There was some litigation over the estate, as Spinoza's only surviving stepsister claimed it all. Spinoza won the lawsuit, but allowed her to retain nearly everything. Henceforth he had to fend for himself.

His studies so far had been mainly Jewish, but he was an independent thinker and had found more than enough in his Jewish studies to wean him from orthodox theology. Ibn Ezra, Maimonides and Gersonides, centuries earlier, had been, to a greater or lesser extent, critical of the orthodox interpretation of Scripture; moreover, the tendency to revolt against mere tradition and authority was very much in the air in the 17th century. But the Jewish religious leaders in Amsterdam were not inclined to tolerance: they were particularly afraid that heresies which were no less anti-Christian than anti-Jewish might give offense in a country of which the Jews were not yet regarded as citizens; and they retained, furthermore, some of the intolerant spirit of the Inquisition, whose victims they had been.

Spinoza soon incurred the disapproval of the synagogue authorities. In conversations with other students he maintained that there is nothing in the Bible to support the views that God has no body, that there really are angels (as distinguished from mere imaginative visions of them) or that the soul is immortal; and he also expressed his belief that the author of the Pentateuch was no wiser in matters pertaining to physics or even theology than they were. These views were reported to the Jewish authorities who, after trying vainly to silence him with bribes and threats, excommunicated him in July 1656. The fact of his excommunication was formally reported to the civil authorities (a gesture intended to absolve the Jewish community from all responsibility for Spinoza's heresies); and Spinoza was banished from Amsterdam for a short period.

After his excommunication he spent a short time at Ouwerkerk, a village near Amsterdam, and then returned to his native city. There is no evidence that he had really wanted to break away from the Jewish community, and indeed the scanty knowledge available would suggest the opposite: on Dec. 5, 1655, he had attended the synagogue and made an offering which, in view of his poverty, must have been a rare event for him; and about the time of his excommunication he had addressed a defense of his views to the synagogue. Apparently he was not entirely indifferent to the authorities' opinion of him.

Portrait by an anonymous painter, about 1670; by courtesy of the Herzog August Bibliothek, Wolfenbüttel

BENEDICTUS DE SPINOZA

Already before his estrangement from the synagogue Spinoza had become acquainted with a number of Christians. Among these was Francis van den Enden, a former Jesuit, an ardent classical scholar and something of a poet and dramatist, who had opened a school in Amsterdam in 1652. For a time Spinoza stayed with Van den Enden, helping with the teaching of the schoolchildren and receiving help in his own further education. In this way he improved his knowledge of Latin, learned some Greek and was introduced to the neoscholastic philosophy of such writers as Franco Burgersdijck (d. 1632) and Adrianus Heereboord (d. 1659). It may have also been through Van den Enden's school that Spinoza became acquainted with the "new philosophy" of René Descartes; but in any case Spinoza's other Christian acquaintances were mostly Collegiants who were especially interested in Cartesianism.

At the same time he was learning the science and art of making lenses, in which he became a great expert; and he supported himself partly by grinding and polishing lenses for spectacles, telescopes and microscopes and partly by helping various people with their private studies. One of his friends at this period was Simon Joosten de Vries, whose admiration for Spinoza was so great that he at one time pressed him to accept a gift of 2,000 florins and at another wanted to make him his sole heir. This Spinoza refused and, when left an annuity of 500 florins in his friend's will, would only accept 300. A kind of reading and discussion circle for the study of religious and philosophical problems came into being under the guidance of Spinoza, whose ideas at this period were gradually becoming formed. In order to collect his thoughts and reduce them to a system, he withdrew in 1660 to Rijnsburg, a quiet village on the Rhine, near Leiden.

Rijnsburg was the headquarters of the Collegiants, and Spinoza lodged there with a surgeon named Hermann Homan. In Homan's cottage Spinoza wrote the *Korte Verhandeling van God, de Mensch und deszelvs Welstand* (i.e., *Short Treatise on God, Man and His Well-being*), the *De intellectus emendatione* (*On the Improvement of the Understanding*), the greater part of his geometric version of Descartes's *Principia philosophiae* (with the appendix of metaphysical thoughts) and the first book of his *Ethica*. Part of the *Korte Verhandeling* consisted of notes that he had prepared in connection with the study circle in Amsterdam, which continued to meet after Spinoza's departure and to which he periodically sent the various parts of the *Tractatus* and other works for study and discussion. Both the *Korte Verhandeling* and the *De intellectus emendatione*, which were originally intended to form one work, were ready in or before April 1662. Already in these writings Spinoza's attitude shows his reaction to Cartesianism.

It was in 1661, during his stay at Rijnsburg, that Spinoza met Heinrich Oldenburg. This man, who was already a member of the Royal society in London and was to be appointed one of its two first secretaries in 1663, is of particular interest here because the most important part of Spinoza's correspondence was with him.

While giving instruction in the philosophy of Descartes, Spinoza made a geometrical version of the second part of Descartes's *Principia*, and this he showed to his Cartesian friends when on a visit to Amsterdam in 1663. They then persuaded him to do the same with the first part, which he did in a fortnight. These two parts, together with an appendix called *Cogitata metaphysica* (i.e., *Metaphysical Thoughts*), were accordingly published by his friends under the title *Renati des Cartes principiorum philosophiae pars I et II, more geometrico demonstratae per Benedictum de Spinoza* (Amsterdam, 1663), with an introduction by Lodewijk Meyer explaining that Spinoza did not share the views expressed in the book. This was the only book published in Spinoza's lifetime with his name on the title page. A Dutch translation by Pieter Balling was published in 1664.

By the early part of 1662 Spinoza had drafted an exposition of his own philosophy in a single work that was to combine the matter of the *Korte Verhandeling* with that of the *De intellectus emendatione*; but he was dissatisfied with the dialogue form employed in this draft and so turned to the geometrical method in the manner of Euclid's *Elements*. Thus originated his major work, the *Ethica ordine geometrico demonstrata*, the first part of which, "De Deo," was finished and in the hands of his friends early in 1663. The

title of the whole work was at first intended to be "On God, the Rational Soul, and the Highest Happiness of Man"; and the work was planned in three parts instead of the five into which it eventually developed. The publication of his version of Descartes's *Principia* had been intended to prepare the way for the publication of his own philosophy, for he had both to secure the patronage of influential men as a shield against the hostility of the Calvinists and to show the more philosophically minded people that his rejection of Cartesianism was not due to ignorance.

In June 1663 Spinoza moved from Rijnsburg to Voorburg, near The Hague; and by June 1665 it appears that he was nearing the completion of the *Ethica*. During the next few years, however, he was at work on his *Tractatus theologico-politicus*, which was published anonymously at Amsterdam in 1670. This was "to show that not only is perfect liberty to philosophize compatible with devout piety and with the peace of the state, but that to take away such liberty is to destroy the public peace and even piety itself." Spinoza also told Oldenburg that he wanted to clear himself of the charge of atheism which had been brought against him. It would appear that, with the completion of the *Ethica* in sight, Spinoza was considering the question of its publication, but found it impracticable in view of the contemporary state of public opinion; he therefore set himself to show that the Bible, properly understood, gives no support to ecclesiastical intolerance or to clerical interference in civil and political affairs.

In May 1670 Spinoza moved to The Hague, where he remained until his death. He began to compose a Hebrew grammar, *Compendium grammatices linguae hebraeae*, but did not finish it; instead he returned to the *Ethica*, although the prospect of its publication became increasingly remote. His *Tractatus theologico-politicus* had aroused great interest and was to go through five editions in as many years, but there were many denunciations of it as an instrument "forged in hell by a renegade Jew and the devil, and issued with the knowledge of Mr. Johan de Witt." Johan de Witt, it should be said, was among those of the civil authorities of the United Provinces who showed sympathy for Spinoza; and his murder in 1672 provoked the philosopher to attempt a demonstration of protest that might have cost him his life had he not been prevented from making it public. Further, Spinoza's political situation in The Hague was compromised in 1673, when, lured by disingenuous invitations from the French army, he went in May to Utrecht (then under French occupation; see DUTCH WARS) with a view to possible negotiations for peace. He was badly received by the suspicious populace of The Hague on his return several weeks later. When the *Ethica* was finally completed in 1675, Spinoza had to abandon the idea of publishing it, although manuscript copies were circulated among his intimate friends. Spinoza then concentrated his attention on political problems and began his *Tractatus politicus*, which he did not live to finish.

In 1675 the scientist E. W. von Tschirnhaus visited Spinoza and brought about a resumption of his correspondence with Oldenburg, which had been interrupted for about ten years for reasons largely connected with Oldenburg's situation in England. In 1676 Spinoza was visited by Leibniz who, having heard of Spinoza as an authority on optics, had sent him an optical tract as early as 1671 and had subsequently received from Spinoza a copy of the *Tractatus theologico-politicus*, which deeply interested him. According to Leibniz's own account, he "conversed with him often and at great length." Spinoza, however, was now in an advanced stage of a pulmonary disease contracted by inhaling the glass dust from the lenses. On Sunday, Feb. 20, 1677, he died, at about 3 o'clock in the afternoon. Four days later he was buried in the New church on the Spui.

In accordance with his previous instructions, Spinoza's manuscripts were sent to the publisher Jan Rieuwertsz in Amsterdam, and his friends Jarig Jelles, Lodewijk Meyer and G. H. Schuller prepared them secretly for the press. *B.D.S. Opera posthuma* (of which there appeared also a Dutch version, *De Nagelate Schriften*), published in Amsterdam before the end of 1677, comprised the *Ethica*, the *Tractatus politicus* and the *De intellectus emendatione* as well as letters and the Hebrew grammar. A treatise on the rainbow and a treatise on the calculation of chances (*Stelkon-*

*stige reeckening van den regenboog and Reeckening van kanssen*) were printed together at The Hague in 1687 but thereafter long forgotten. The *Korte Verhandeling* was lost to the world until E. Boehmer's publication of it, with a Latin translation, as *Tractatus de Deo, de homine ejusque felicitate* (Halle, 1852), after which it was re-edited, together with the treatise on the rainbow, by J. van Vloten (Amsterdam, 1862).

A word must be said here of the attractiveness of Spinoza's personal character. It is discernible in all the records of his life and is recognized even by those who find themselves forced to reject his philosophical system.

### PHILOSOPHY

The philosophy of Spinoza may be regarded as a development from, and reaction to, that of Descartes. Although Spinoza was also much influenced by medieval, especially Jewish medieval, philosophy, he seems to have been much more conscious of the Cartesian influence, and his most striking doctrines are most easily understood as solutions of Cartesian difficulties. As has been said above, he had studied Descartes in detail and written an account of his philosophy in geometrical form. He accepted Descartes's physics in general, although he expressed some dissatisfaction with it toward the end of his life (see letter lxxxiii in A. Wolf's edition of the *Correspondence*), but he found three very unsatisfactory features in Cartesian metaphysics, namely the transcendence of God, the substantial dualism of mind and body and the ascription of free will as *liberum arbitrium* both to God and to human beings. In Spinoza's eyes, these doctrines made the world unintelligible. It was impossible to explain the relation between God and the world or between mind and body or to account for those events which are occasioned by free will.

Spinoza assumes without question that it is possible to construct a system of metaphysics, *i.e.*, an account of the world as a whole, which will render it completely intelligible. It is therefore possible in his view to present metaphysics deductively, that is, as a series of theorems derived by necessary steps from self-evident premisses expressed in terms which are either self-explanatory or defined with unquestionable correctness. His chief work, the *Ethica*, is set out in this manner (*ordine geometrico demonstrata*). The desire to secure impersonality was probably his chief motive for adopting this method of presentation. He appreciates, of course, that the use of the method guarantees true conclusions only on condition that the axioms are true and the definitions correct. Spinoza, like his contemporaries, holds that definitions are not arbitrary, but that there is a sense in which they may be correct or incorrect.

The question is discussed at length in his unfinished work, *De intellectus emendatione*. A sound definition, he holds, should make clear the possibility of the existence of the object defined, or, in the case of a necessary existent, the necessity of its existence. The *Ethica* begins with the definition of substance, the necessary existent. Since the concept of substance (*q.v.*) is among the most disputed in metaphysics, it is clear that the system could be rejected by anyone disputing the definition, however cogent the subsequent reasoning. In fact, however, as Leibniz pointed out, the demonstrations do not proceed with mathematical rigour. The system is closely knit, but not mathematically demonstrated, and the method of presentation creates some difficulties for the reader, who will at first find it easier to follow Spinoza in the prefaces to the different books and in the extended scholia where he drops the strict geometrical method. It seems in fact that, since the basic concepts, substance, attribute and mode, are in dispute and cannot, like those of geometry, be given intuitive content, metaphysics is not most suitably treated step by step, in the geometric way. The system must be accepted or rejected as a whole. If the conclusions are found to be sound, this lends support to the initial axioms and definitions.

From Spinoza's point of view a satisfactory metaphysical system would have to fulfill the following requirements: it must be intelligible in the sense explained above; it must be consistent with Cartesian or some similar physics; it must explain the main facts of human life, especially the occurrence of true and false thinking

and of moral experience; and it must provide a worthy object of worship. This last point was undoubtedly of great importance for Spinoza: a deep religious feeling was one of the main motives in the construction of his system.

**God or Substance.**—Spinoza begins with the idea of substance as that which can be conceived as existing in complete independence (*Ethica*, i, definition 3). Since its existence is to be intelligible and it cannot be caused or explained by anything else, it must be its own cause (definition 1); *i.e.*, necessarily existent. There can be only one such substance, and this is quickly identified with God, the traditional necessary existent, and with the whole of Nature. Rejecting the idea of a transcendent God as unintelligible, but still accepting the traditional concept of a necessary being, Spinoza finds this being in the whole of the universe, which must contain all reality. He is able to accept this as a worthy object of worship and thus arrives at the position of pantheism (*q.v.*). Spinoza's account of the nature of God was the most shocking feature of his philosophy to his orthodox contemporaries and successors, both Christian and Jewish. With the transcendence of God, he denies also God's personality in the ordinary sense and God's providence. Spinoza undoubtedly thought that these doctrines were inseparably connected with a crude anthropomorphism. God is a conscious and, indeed, an omniscient being, but has no free will as ordinarily understood and no purposes: He acts according to the necessity of His own nature, which is to act freely in Spinoza's sense (*Ethica*, i, appendix). God cannot, therefore, have any special providential care for man; and the good man, although he loves God, will not expect God to love him in return (*Ethica*, v, 19).

**The Attributes.**—Substance has, or is constituted by, an infinite number of attributes (*Ethica*, i, definition 6); but only those two attributes of substance which enter into his own nature are known to man; *viz.*, thought and extension. To say that these are attributes of substance is to say that the universe is a spatial whole which is conscious throughout. Spinoza accepts this conclusion and thus arrives at a panpsychist position: "All things . . .," he says, ". . . are alive" (*Ethica*, ii, 13, scholium). The theory that there are infinite attributes is very difficult and seems to lead to inconsistencies in the development of the system. For, since all attributes qualify substance throughout, it seems to follow that there should be some entity under each attribute which corresponds to the human mind in the same way that the body corresponds to it. We should therefore expect that all the attributes would be known to man. When pressed on this point, Spinoza replies that the modes under thought which correspond to modes under attributes other than extension are not human minds, but minds of a different kind (letter lxvi in Wolf's edition). This solution, however, is inconsistent with complete parallelism, for it gives the attribute of thought a unique position, in that it corresponds to all the attributes in a way in which they do not correspond to each other.

This difficulty has led some commentators to adopt a subjectivist interpretation of the attributes; *i.e.*, to say that the attributes are simply the infinitely many possible ways in which substance could be conceived. This interpretation receives some support from the extremely obscure definition of attribute given by Spinoza: "By attribute I understand that which the intellect perceives of substance as constituting its essence." It seems clear, however, from the letter quoted that Spinoza thinks of the attributes as objective. Probably the doctrine of infinite attributes is a relic of traditionalism in Spinoza which cannot be satisfactorily interpreted in detail.

**The Modes.**—Besides consisting of infinite attributes, substance is diversified into infinite modes. The interpretation of the word "mode" has been much disputed, but it is best understood as "part" as long as it is borne in mind that such a part cannot be separated from the whole of which it is a part. Human beings and other common-sense objects, which are typically modes, are parts of nature, and Spinoza once refers to the human mind as part of the infinite intellect of God. There is a one-to-one correspondence between modes under the several attributes, and necessarily so, since every attribute must qualify the whole of substance.

This is the doctrine of the parallelism of the attributes. So far we have spoken of finite modes only, but Spinoza speaks also of infinite modes, which are, of course, not parts of substance but co-extensive with it.

There are both immediate and mediate infinite modes. This part of the theory is difficult to understand, especially as Spinoza does not illustrate it very fully. The immediate infinite mode under the attribute extension is motion and rest. This is probably to be interpreted as the sum total of motion in the universe, so that this part of the theory is an attempt to incorporate the Cartesian doctrine of the conservation of motion. Similarly, the absolutely infinite understanding, which is the immediate infinite mode under thought, would be the sum total of consciousness or knowledge. The universe as a system of attributes is called *natura naturans*, as a system of modes *natura naturata*.

**Causality and Determinism.**—The whole scheme is completely deterministic: since the nature of God cannot be other than it is, the whole system of modes, which follows from or expresses the nature of God, must necessarily be as it is. This is a corollary of Spinoza's demand for intelligibility; for only on this condition can we conceive that every modal event has a cause or explanation which lies in another modal event. By "cause" Spinoza means roughly what we should mean by "explanation," and he shares with Descartes the general rationalist view that a cause must have properties in common with its effect.

It follows that a mode under one attribute cannot be caused or explained by a mode under another attribute, for they have no property in common. Any modal happening under one attribute has its explanation entirely in terms of modal happenings under that same attribute. Since the modes are infinite in number, the complete explanation of any event in concrete terms would be infinitely complex and so cannot be attained by human beings. It is possible for us, however, to explain a particular modal event to some extent by referring to the general laws which govern the occurrence of modal events under the appropriate attribute; e.g., by referring to the laws of physics in the case of material events and to those of psychology in the case of mental events.

**Application of the Metaphysical Scheme to Human Beings.**—The abstract scheme gains meaning as it is applied to human beings. Spinoza develops this application in the *Ethica*, parts ii-v. A man is a mode under the two attributes, extension and thought. His body is a mode under extension and is not a single thing but a complex mode, owing its unity to the maintenance of a constant pattern of relations between changing parts (see the axioms, etc., following *Ethica*, ii, 13). The human mind is what corresponds under the attribute thought to the human body. It is therefore likewise a system maintaining the same pattern of relation through change of parts. Spinoza, however, does not develop his theory of the unity of the mind in the same detail as his theory of bodily unity. The mind is called the "idea of the body." Spinoza sometimes speaks of two modes, the human mind and the human body, while at other times he asserts that they are one and the same thing, conceived now under thought and now under extension. These are simply alternative expressions. A human mind is that part of God's mind which is the knowledge or awareness of a given human body. The relation between a mind and its body is, therefore, intrinsic to it; and Spinoza does not require, as Descartes and Leibniz did, to invoke the miraculous intervention of God to explain the connection between a given human mind and its body.

From the general position it follows immediately that, while there is no causal connection between mind and body, there is a mental correlate for every physical event and a physical correlate for every mental event. If "mental correlate for" is here understood as "knowledge of," we reach the paradoxical result that all events in a given human body are known to the corresponding human mind and that no other events are known to that mind. At one point Spinoza appears to accept this result: "The object of the idea which constitutes the human mind is the body or a certain mode of extension actually existing and nothing else" (*Ethica*, ii, 13). The paradox is softened, however, when we realize that the word "idea" and the closely related term "knowledge" (*cognitio*) are used by Spinoza to signify not only a state of clear and ac-

curate knowledge but any state of consciousness whatsoever, however dim and vague. All states of consciousness must have objects, but the objects need not be in the full sense known. Interpreted in this way, the paradoxical statement resolves itself into the following two propositions: (1) every change in the human body is associated with some change of awareness, however dim and vague, in the human mind (*Ethica*, ii, 12); and (2) a human being can know external physical objects only insofar as they affect his own body (*Ethica*, ii, 26).

**Theory of Knowledge.**—Spinoza distinguishes three grades or kinds of human knowledge (*Ethica*, ii, 40, scholium 2). He distinguishes states of awareness as adequate or inadequate rather than as true or false; and the argument of *Ethica*, ii, 19-31, is directed to show that we cannot adequately know particular things, either our own bodies or their parts, or external objects. We are aware of things only in interrelation and cannot know them as they are in themselves. Thus all sense experience which is the mental correlate of the action of external things on our own bodies and all unscientific generalization from sense experience is inadequate. We cannot state the truth about a given object in itself, because it cannot be isolated from the rest of nature; and we cannot state the whole truth about it, since this would involve the whole of nature. Knowledge of this kind is called by Spinoza opinion or imagination. If, however, the consciousness is directed solely toward those properties which all objects, including the human body, have in common, there is no distortion such as occurs when objects with different properties interact. In such cases we have the second kind of knowledge or reason (*ratio*). In this way Spinoza accounts for the possibility of clear a priori knowledge in geometry, general physics and general psychology.

The third kind of knowledge, intuition (*scientia intuitiva*), seems to be the adequate knowledge of individual objects. It is difficult to see how this is possible on Spinoza's presuppositions. For the proof of the possibility he relies on the fact that it is possible to state of any individual thing that it depends on God as its complete, immanent cause (*Ethica*, ii, 47), but it is difficult to see how this general statement could be held to constitute adequate knowledge of the individual thing. It is possible that by the term "intuition" Spinoza refers to mystical experience, the insight—accompanied by strong emotion—into the dependence of all things, including the human being himself, on the whole of nature.

There are other difficulties in Spinoza's theory of knowledge, for it is hard to see how, if the theory be true, we could either be mistaken about the general properties of things (i.e., have a faulty geometry or physics) or be completely right about some particular thing. The distinction between truth and falsehood about particular things occasions Spinoza great difficulty. According to his general account, the difference must be one of degree only, falsity being a matter of greater confusion or less adequacy. His account of the matter is to be found in *Ethica*, ii, 35, and there is also a long discussion of falsity in the *De intellectus emendatione*. What is clear is that our understanding of an individual thing or event will be adequate in proportion as we can explain its features in terms of the general laws, which are the concern of reason; i.e., insofar as we can make correct causal statements about it. The position has important consequences for Spinoza's psychology of the emotions and for his ethics.

**Psychology of the Will and the Emotions.**—Spinoza followed Descartes in the attempt to construct a rational psychology. This is possible, according to his general theory, because there corresponds to every corporeal mode not only an idea but also an idea of that idea (*Ethica*, ii, 20). Thus introspective or reflective knowledge is possible. This seems to occasion another break in the strict parallelism of the attributes, giving again a certain primacy to the attribute of thought.

Spinoza rejects the concept of will as ordinarily understood. He does not, of course, deny that voluntary action or deliberately chosen action occurs, but this does not involve free will in the ordinary sense (*Ethica*, ii, 48) and is to be understood in the following way. Willing is primarily thinking of the course of action to be followed: "The will and the understanding are one and the same thing" (*Ethica*, ii, 49, corollarium). This mental

state is the correlate of a physical state whose normal outcome is the realization of the action contemplated. When there are no hindering factors, the action in question inevitably follows (*Ethica*, iii, 2, scholium). The illusion of undetermined choice arises from our ignorance of the preceding causes of thought and action. Since Spinoza's ethics are, however, largely concerned with the distinction between bondage (*servitus*) and freedom (*libertas*), it is clear that he must provide some alternative account of freedom which does not involve free will as ordinarily understood. This is to be found in the distinction between the active and the passive emotions, which is closely bound up with his metaphysical theory.

The denial of human free will is another feature of Spinoza's system which has been found highly shocking, as involving the denial of moral responsibility and of the appropriateness of blame or punishment. It is true that Spinoza, anticipating later criminology, pleads for an objective and dispassionate treatment of undesirable human behaviour, but he by no means denies the sociological and political necessity of punishment, holding that most men must be governed by fear.

Every individual thing or mode obeys the fundamental law of nature that it should strive to preserve itself and continue in existence. This *conatus quo in suo esse perseverare conatur* ("endeavour to persist in its own being") is the essence of the individual thing. All finite modes, on account of their limited power, in the end perish. Only substance has the power of unlimited self-maintenance. In human beings *conatus* is on the physical side appetite and on the mental side desire (*cupiditas*), one of the primary emotions. The only other primary emotions are joy (*laetitia*) and grief (*tristitia*). Joy is the psychic accompaniment or consciousness of the transition to a greater degree of power, while grief is the consciousness of a transition to a lesser degree of power. The other emotions, love, hate, etc., are defined in terms of these and their different possible objects. Spinoza's analytical psychology, which has often been justly admired, is partly based on Descartes's *Les Passions de l'âme*, but without the interactionist presuppositions of that work. Insofar as human beings are able to understand themselves and their environment, they can control events rather than be controlled by them. The striving for, and transition to, a greater understanding is accompanied by desire and joy in their active forms. A man is free insofar as his emotions are active rather than passive. Freedom, for Spinoza, is then a relative notion: human beings are free in proportion as they are able to think clearly, to control their environment and to preserve themselves for the maximum time in an active state. In part iv of the *Ethica* ("Of Human Bondage"), Spinoza stresses the extreme difficulty of attaining any degree of freedom on account of the strength of the passive emotions. In part v, however, he shows that liberty may be attained and the passive emotions mastered through understanding their causes. He is the first to emphasize that the complete understanding of emotions and of their causation deprives them of their overmastering quality. In this he may be said to have anticipated psychoanalysis. He also anticipates a later attitude in his insistence on the completely objective study of the emotions, their causes and effects, "as if it were a question of lines, planes and solids" (*Ethica*, iii, preface).

**Moral Philosophy.**—Spinoza is content with an apparently subjective definition of "good": "The good is that which we know certainly to be useful to us" (*Ethica*, iii, definition 1). He also accepts the fact that the good for different species (e.g., for man and for horse) is different. For God the distinction between good and evil would be meaningless, as it is essentially relative to the purposes of finite creatures; and the human being, insofar as he understands nature scientifically, makes no moral judgments (*Ethica*, i, appendix). But human beings have enough in common for the philosopher to be able to pronounce on what is really good for them—however different their views may be because of the inadequacy and confusion of their ideas. Thus "good" may be said to have an objective significance for human beings. The characteristically human good is the increase in understanding which leads to the longest possible preservation of the individual in physical and mental health. This is summed up in the phrase "knowledge of God" (*Ethica*, iv, 28). In his actual rules Spinoza

may seem to overemphasize the importance of intellectual pursuits, but he is not an ascetic; for, according to his parallelistic doctrine, everything that increases physical well-being will also promote mental health.

Since the consciousness of a transition to a state of increased power or health is joy, while sadness in all its forms is the accompaniment of diminishing power, Spinoza condemns such emotions as remorse and humility as harmful and morbid in themselves, while admitting that they may have useful effects (*Ethica*, iv, 53–54).

Spinoza's ethics are essentially egoistic, but the conduct that he commends is that which would be commended by an altruistic utilitarian: Love may be at times an active emotion, but hatred never (*Ethica*, iv, 45); and Spinoza tries to prove that hatred may be overcome by love (iv, 46). His ideal man is in many respects comparable to the Stoic sage, for his aim is the maximum self-sufficiency, but Spinoza gives a more balanced picture in that he has a stronger realization of the essential interdependence of men. Co-operation and friendship between rational men is not only a means to, but an essential part of, the individual's true good (*Ethica*, iv, 60). The preservation of civil society and of peace is a necessary means to individual well-being. This is the basis of Spinoza's political philosophy, which will be considered below.

It is first necessary, however, to touch upon a difficult feature of Spinoza's individual psychology and ethics, the doctrine of the eternity of the mind. This is contained in the latter half of book v of the *Ethica*, a section which has been especially puzzling to commentators. Any theory of survival in the ordinary sense seems plainly inconsistent with Spinoza's parallelistic doctrine. He nevertheless declares that the human mind cannot be absolutely destroyed with the body, but that something remains of it which is eternal (*Ethica*, v, 23). This doctrine has never been satisfactorily explained. Spinoza connects the eternity of the mind with the third kind of knowledge, intuition, which consists essentially in understanding individuals in relation to God, and with the characteristic accompanying emotion, the intellectual love of God, which is the highest degree of acquiescence. This should be compared with the dictum of the *De intellectus emendatione* that blessedness is the knowledge which the mind has of its union with the whole of nature. Spinoza perhaps means that since men must necessarily fall short of complete activity, their highest state is the understanding of, and acquiescence in, their own necessary degree of passivity. Insofar as this is real understanding, it is shared with God and is, in that sense, eternal. But such a doctrine carries no implication of individual survival.

**Political Philosophy.**—In *Ethica*, iii and iv, Spinoza stresses not only the desirability but also the extreme difficulty of co-operation between men. This is made especially clear by the fact that the good at which human beings aim, insofar as they are affected by passive desires, is necessarily competitive; i.e., if men conceive that their survival and welfare are dependent on the possession of external goods, they will necessarily be in conflict with each other (*Ethica*, iv, 32–34). The true good of human nature, the knowledge of God, is, however, noncompetitive, so that men cannot come into conflict insofar as they are affected by the active emotion of desire for this good. If this emotion were predominant in men, that is, if men were mostly rational, there would be no need for political organization, since free and rational men naturally wish to co-operate. Most men, however, are under the control of their passive emotions for the greater part of their lives and will necessarily strive for their own aggrandizement to the detriment of others. Like Thomas Hobbes, Spinoza finds the only remedy for this situation in absolute government. He maintains that it is only under government that the distinction between right and wrong, in a strict sense, arises; whereas in the state of nature "right" means "power" and man has the "right" to do whatever he thinks necessary to his own preservation, in civil society the rational man must yield full obedience to the government as the necessary bulwark against anarchy, so that what is commanded by the government is right. In relation to each other, sovereign states are in a state of nature and are bound only by the law of self-preservation; e.g., treaties need not be kept when they are no

longer advantageous. A wise government, however, like a rational man, will see that the surest way to self-preservation is the maintenance of peace.

Similarly it will recognize that the surest way to secure the adherence of its subjects is just government with the maximum freedom possible. Spinoza, therefore, unlike most absolutists, lays great stress on the desirability of freedom of thought and speech in matters of religion. He argues that it is impossible to coerce thought and that a man will be a more loyal citizen if he is allowed to speak his mind freely. The state has a right, however, to control the outward expression of religion. What Spinoza most fears is ecclesiastical tyranny and sectarian strife, and he regards the control of religion by the state as a much lesser evil. Among possible forms of government he prefers democracy as potentially the most stable. These views are expressed not only in the unfinished *Tractatus politicus*, but also in the *Tractatus theologico-politicus*. In this work, in which he anticipates modern biblical criticism, he bases a plea for freedom of thought and speech in religious matters on a careful examination of biblical doctrine and its relation to philosophy.

**Biblical Criticism.**—Spinoza is far ahead of his time in advocating the application of the historical method to the interpretation of the biblical narrative. He argues that it is only in respect of their moral and practical doctrine that the prophets of the Old Testament were inspired. Their factual beliefs were those appropriate to their time and must not be regarded as philosophically significant. Complete freedom of scientific and metaphysical speculation is therefore consistent with all that is important in the Bible. The miracles of the Old Testament are explained as natural events misinterpreted by the prophets and stressed for their moral effect.

**The Influence of Spinozism.**—Spinoza has an assured place in the intellectual history of the western world, both as the author of one of the most complete metaphysical systems ever conceived and as an early advocate of freedom of thought. His direct influence on technical philosophy has not, however, been great at any time. Throughout the 18th century he was almost universally decried as an atheist (sometimes, perhaps, by writers whose primary intention was to commend atheism by giving it the prestige of his name, while protecting themselves from condemnation by their formal disparagement of the very ideas that they were presenting with detailed care under cover of mere historical narration). The tone had been set by Pierre Bayle, in whose *Dictionnaire Spinozisme* is described as "the most monstrous hypothesis imaginable, the most absurd and the most diametrically opposed to our minds' most evident notions"; and even David Hume felt obliged to speak of the "hideous hypothesis" of Spinoza. Throughout this period he was probably, as Voltaire says, "less read than famous," partly because an exaggerated respect for his geometrical method led to the view that his conclusions were inescapable once his premisses were accepted. He was rendered intellectually respectable by the efforts of literary critics, especially Lessing, Goethe and Coleridge, who admired the man and found an austere excitement in his works. The attraction of his work is due largely to the fact that he expresses an intensely religious attitude entirely divorced from dogma, and it has been felt less by technical philosophers than by poets, such as Goethe and Wordsworth, and by scientists of wide intellectual sympathies, like, for example, Einstein. He has nevertheless been much studied by professional philosophers since the beginning of the 19th century. Both absolute idealists and Marxists have read their own doctrines into his work, and positivists and empiricists, while rejecting his metaphysical approach, have developed fruitfully certain detailed suggestions of his theory of knowledge and psychology.

**SPIRAEA**, a much cultivated genus of shrubs (the common term is spirea) of the rose family (Rosaceae; *q.v.*), comprising about 80 species and scores of horticultural varieties, natives mostly of the Northern Hemisphere. They are slender shrubs, two to eight feet high, usually with simple leaves and small white, pink, or red flowers arranged in dense showy clusters. *Spiraea douglasii* (western meadowsweet) occurs on the Pacific coast. Among the best-known cultivated forms are *S. prunifolia* and the popular hybrid *S. vanhouttei*, both commonly called bridal wreath. *S. salicifolia* (queen of the meadow) occurs in England and Scotland. *S. latifolia* and *S. alba* (both known as meadowsweet) and *S. tomentosa* (hardhack; *q.v.*) are representative species of eastern North America.

The cultivated spireas are divided into generally white-flowered, spring-blooming kinds typified by the true bridal wreath (*S. prunifolia*) and its relatives, and the summer-blooming, prevailingly red or pinkish-flowered species allied to *S. billardi*. Among these showy, summer-blooming species are *S. japonica* and *S. bumalda*, a particularly fine variety of which is Anthony Waterer. Spireas thrive in most garden soils, are relatively immune to pests, and are easily propagated by seeds or cuttings of green wood. Some bushes arch over, the stems rooting at the tips.

A few of the so-called spireas belong to several other genera, as *Astilbe*, *Aruncus*, *Filipendula*, and *Caryopteris*. (N. Tr.)

**SPIRE**, in architecture, a steeply pointed termination to a tower (*q.v.*). Towers built in diminishing stages are sometimes called "spires," but in error; strictly speaking, those are steeples. Spires are in essence a kind of pointed roof, originating in the simple, four-sided pyramidal roof capping church towers in the early middle ages. In their mature Gothic development, however, only reminiscences of a roof remained, and spires became independent architectural elements, with both aesthetic and symbolic significance. (See also PINNACLE.)

From their first appearance to the 12th century, spires were generally abrupt and stunted in form; their history is a development toward slimmer, higher forms and a more organic relationship with the tower below. A late 11th-century tower at Le Puy en Velay shows the nature of early experiments in this direction; the successive stages of the tower recede and are broken up by projecting bays on the sides. Furthermore, the pyramidal roof itself is decorated with corner finials and small, round-headed dormers. In Germany the form was varied by ending each face of the square tower in a gable, the plane determined by adjacent gable slopes establishing the slope of the pyramid, as in the square tower of the abbey church of Laach (c. 1156). The pleasanter effect of the octagonal spires over octagonal towers, like another of the towers at Laach or the older of the two towers at Mainz (late 12th century), led to attempts to combine an octagonal spire with a square tower. This was accomplished in various ways, one of the simplest being the so-called broach spire, in which small, triangular planes of a less steep pitch than that of the spire proper occur at the bottom of the corner spire faces, with their lower points coinciding with the corners of the towers, as seen in the 12th-century church of St. Columba at Cologne.

A more developed form of broach spire lies in the substitution of a small pyramid at the bottom of the corner faces, instead of the triangular plane. This is a type which became common in English Gothic spires. It may be described geometrically as the inter-

(LEFT, TOP CENTRE) BILDARCHIV FOTO MARBURG; (SECOND FROM LEFT, BOTTOM CENTRE, RIGHT) A. P. KERSTING

(Above) Square tower (centre of picture) of Abbey Church at Laach, Ger., about 1156; (right) facade of Chartres Cathedral, France, showing southwest spire at right, late 12th-century, and the more elaborate 16th-century northern spire at left; (top centre) spires of St. Elizabeth, Marburg, Ger., built in the 14th century from 13th-century designs; (bottom centre) spire of St. Martin's-in-the-Fields, London, designed by James Gibbs, 1721-26; (right) spire of Salisbury Cathedral, England, 1250

section of a four-sided pyramid of low slope by an eight-sided pyramid of steep slope, as in the 14th-century spire of St. Mary's at Stamford. A more elaborate method of softening the junction between square and octagon was to carry the corner faces down unbroken to the top of the tower and fill the triangular corners thus left with decorative finials. An early example is the crossing tower of the church of St. Ours, at Loches, France (12th century).

In the southwest tower of Chartres cathedral (end of the 12th century) a further advance is made in connecting tower and spire, by adding high, gabled dormers on the faces of the spire, over the centres of the tower faces, as well as richly developing the corner pinnacles. In the spire at Senlis cathedral (13th century) a vertical, octagonal stage, or lantern, is placed between the square tower and the octagonal spire. The corners of the square tower are occupied by pinnacles and eight slim dormers surround the spire base. The edges of the Chartres and Senlis spires are decorated with projecting roll moldings, and those at Senlis are further enriched by crockets which form an admirable fretting of the silhouette. It is probable that similar crocketed spires were almost universally intended over the great towers of most of the French cathedrals. The towers at Laon, for instance, were once so crowned and spires at Reims and Amiens were begun.

**Gothic Climax.**—It was in Normandy, England and Germany that Gothic spire design reached its climax. Particularly famous are the spires of St. Sauveur at Caen (14th-century church destroyed in World War II) and the magnificent group of spires at Coutances cathedral (13th century), in which the spire dormers and the corner pinnacles are treated with the utmost richness and the sense of height and slimness emphasized in every possible manner. The customary lavishness of the French Flamboyant style is magnificently illustrated in its pierced and intricately traceried spires. The two most remarkable examples are the northern spire of Chartres cathedral (1506-13), by Jehan Texier, and the so-called Tour de Beurre (c. 1520) of the cathedral at Rouen.

Spires of a simple type crown many of the Italian campaniles, and during the 13th, 14th and 15th centuries, spires and lanterns

were frequently added to earlier towers. In neither Italy nor Spain, however, was the highly developed spire a native form, and Italian spires were simple, slate, tile or metal covered, pyramidal or conical roofs of timber. Burgos cathedral is unique in Spain in possessing two western spires of intricate openwork masonry, which date from the 15th century. These, however, are known to have been designed by a German architect.

German luxuriance, which had already appeared in the numerous varieties of timber spires used on the Rhenish Romanesque churches, found equally congenial expression in the stone spires of the Gothic period. The early, simple type is seen in the solid spires of St. Elizabeth at Marburg (not completed until the middle of the 14th century but probably from a 13th-century design). The cathedral at Freiburg has a spire (1270-88) which is of a new and infinitely richer type. The low, square tower carries a high, octagonal lantern, each side of which is capped by a slim gable and filled with delicate tracery. The corners of the square are filled with rich, triangular pinnacles, one of which is continued up as an open, spiral staircase, giving access to the upper portion. The spire rises above the lantern, a mere cage of openwork tracery, with crocketed edges, amazingly light and delicate in effect. Somewhat similar, although even more intricate in their pierced stonework are the western spires of Regensburg cathedral (late 15th century), by Roritzer. These openwork spires became the rule in Germany, as illustrated in the intricate cage of Strasbourg cathedral (spire, 1435); the west towers of Cologne cathedral, built in the 19th century from medieval drawings; the over-complicated lacework of the cathedral at Vienna (1433) and the spire at Ulm, over 500 ft. high, built in the last years of the 19th century, from 15th-century drawings.

The spire of Oxford cathedral (1220) is a perfect example of the Early English spire type; it is octagonal, has a marked entasis or convex curve, and is decorated with dormers on each face and corner pinnacles. The great spire of Salisbury cathedral (1250), 406 ft. high, shows the tremendous aesthetic advantage of the greater steepness there present, which became the rule in the later English spires. During the Decorated period it became customary to finish

the top of the tower with a parapet, either battlemented or of pierced tracery, and to set back the base of the spire behind the face of the wall. With this change the use of broaches disappeared and tall, corner pinnacles, sometimes supported on corner buttresses, filled the tower corners, as seen in the two western spires of Lichfield cathedral. In other examples a little flying buttress connects the corner pinnacles with the face of the spire, as in the exquisite Perpendicular spire of Louth church, Lincolnshire. Many Perpendicular spires are often ornamented with crockets up the angles. (See also *GOthic ARCHITECTURE*.)

**Renaissance.**—The spire was a form never thoroughly absorbed by the Renaissance which preferred domed lanterns crowning towers. Nevertheless, during the 17th century in Germany, most effective, fantastic, spirelike forms were developed. These, based partly on Italian baroque prototypes, usually had profiles of broken concave and convex lines, crowned at the top with a sort of onion dome, the whole rising to a considerable height, and, in imaginative quality, far surpassing any of the Italian examples. It is such fantastic spires crowning the simple towers of village churches which give much of their character to the little towns of south Germany and Austria. At the same time, in England, the spire idea was receiving a much simpler and more straightforward, and equally effective, Renaissance expression, through the efforts of Sir Christopher Wren and his followers, particularly in the churches built after the Great Fire of London in 1666, such as St. Martin's, Ludgate hill, St. Mary-le-Bow and St. Bride's, Fleet street (spire and steeple only remain), all by Wren. St. Mary-le-Strand (early 18th century) and St. Martin's-in-the-Fields (1721-26), both by James Gibbs, which simplified and refined upon their Wren prototypes, are very successful.

Even more effective are many colonial spires, which, although originally based upon the work of Wren and Gibbs, achieved a fresh beauty through still further simplification. Particularly noteworthy is the type in which a small, octagonal, arcaded lantern crowns a simple, square tower and carries, usually above an attic, a simple, slim, white spire, as in the Old South meetinghouse, Boston (1729), and the extremely delicate, white, wooden steeple of the church at Farmington, Conn. (c. middle 18th century). Such steeples as that of St. Paul's chapel, New York (c. 1767), Christ church, Philadelphia (1754), and St. Michael's, Charleston, S.C. (1742, occasionally attributed to James Gibbs himself), although more monumental in treatment and more English in effect, still retain the characteristic American delicacy. This trend toward the more slender and attenuated proportions reached its climax in the exquisitely light spire of Park Street church, Boston (1819), by Peter Banner.

The 19th-century architects made extravagant use of spires for their picturesquely irregular outlines and visually exciting shapes; Anglican Gothic Revival architects of the late 1840s, '50s and '60s used them with particular effectiveness to culminate dramatically massed compositions. Perhaps because spires were so closely associated with picturesque eclecticism, 20th-century architects have tended to limit them to rather elementary geometric shapes.

**SPIRITUALISM.** The word spiritualism has been used with two meanings: first, for a metaphysical theory that asserts the reality of a nonmaterial spiritual world, which is a view common to religions; second, for a system of beliefs and practices having the object of communicating with the asserted spirits of those who have died, and for the social institutions of those who hold these beliefs and carry out these practices. It is in this second sense that the word is to be understood in the present article. To avoid confusion with the more general metaphysical meaning of spiritualism, the word spiritism has been suggested as more appropriate for the beliefs and practices connected with communication after death, but this use has not generally been adopted.

Spiritualist practices commonly take place in the presence of a person (the medium) who is regarded as a human intermediary with the spirit world. Although mediums are most commonly women, some highly gifted mediums have been men, as, for ex-

ample, the famed D. D. Home (see *LEVITATION*). The séance at which mediumistic phenomena occur may be in complete darkness, in reduced light, or, more rarely, in full daylight. The medium is sometimes in a state of trance, speaking and behaving without subsequent memory of what has been said or done, but some mediums work in a state of normal consciousness.

The main activities of spiritualism are: (1) the phenomena of mental mediumship; (2) the production of materializations and other phenomena of physical mediumship; (3) spirit photography; and (4) spirit healing (see also *SHAMANISM*).

The phenomena of mental mediumship include ostensible messages from spirits of the departed. They may be messages to their own friends and relatives present at the séance, or the communicators may say they are describing the conditions of life beyond the grave. In some cases spirits are said to dictate books of fiction or history. Usually the messages come through a spirit control who appears to communicate directly with the sitters; more rarely the communicators appear to communicate by direct voice.

Phenomena of physical mediumship include the playing of musical instruments, transportation of physical objects (apports), levitation of the medium or nearby objects, raps, and so on. These have sometimes been considered to be too reminiscent of horse-play to be appropriate activities of discarnate spirits. They are, however, generally explained as of value only as providing evidence for the possibility of spiritual activity. The most important physical phenomenon is the appearance of a filmy substance (ectoplasm), which is generally supposed to be a quasi-material substance derived from the body of the medium, which may take the form of a face, hand, or complete body. Such materializations have been photographed, but there have also been photographs of what purported to be ectoplasm in which the structure suggests some such material as cheesecloth. Materializations and other physical phenomena occur in darkness or in dim red light, as the exposure of ectoplasm to strong visible light is said to be injurious to the medium. Spirit photographs also have been obtained by some operators on films that may not have been exposed in a camera. It is obvious that such films could be produced fraudulently, as, for example, by the use of radioactive material, but they are also stated to have been produced under satisfactory test conditions.

An important later development of spiritualism has been in the direction of spirit healing. Unorthodox healings have in the past been associated with sacred places and religious rites, and medical science is inclined to attribute all such healings to the normal process of suggestion working under favourable conditions. But it is also alleged that there is a genuine power of paranormal healing found in certain persons, and from the spiritualist point of view these healers are regarded as mediums who act as agents of spirit doctors. Healings are claimed for a variety of conditions, some of which are regarded as incurable by orthodox medicine.

**History.**—The attempt to communicate with discarnate spirits seems to be one of the forms that religion may take in human societies and to be widely distributed in space and time. Practices very like those of a modern spiritualistic séance have been reported in various parts of the world, as, for example, Haiti and among the North American Indians, and there is no reason for supposing that these are of recent origin. The record of a materialization séance of long ago is preserved in the account in the Old Testament of Saul's visit to the witch (or medium) of Endor, in the course of which a materialization appeared that was regarded by the king as the prophet Samuel (I Sam. 28:7-19). Certain mediumistic phenomena are reported in the witch trials of the Middle Ages, particularly the appearance of spirits in quasi-material form and the obtaining of knowledge through spirits. It may be supposed that many of those persecuted for the practice of witchcraft were what would now be called mediums, although their mediumship was coloured by the fact that it was organized in a forbidden cult and the spirits with which communication was established were regarded as devils. Some mediumistic phenomena were also found among those regarded in the Middle Ages as

possessed by devils; e.g., speaking in languages unknown to the speaker and levitation or partial levitation (see *DEVIL: Diabolism Within the Church*).

Although spiritualistic practices seem to be widespread in space and time, they were virtually unknown in modern civilized society until March 1848, when odd happenings were reported at the house of a farmer named Fox at a small town in New York State. Previous occupants of the house had been disturbed by unexplained raps at night. After a severe disturbance by raps during Mr. Fox's tenancy, his youngest daughter, Kate, was said to have successfully challenged the supposed spirit to repeat the number of times she flipped her fingers. Once communication had apparently been established a code was agreed upon by which the raps given could answer questions, and the spirit was said to have identified himself as a man who had been murdered in the house.

The practice of having sittings for communication with spirits spread rapidly from that time. Kate Fox (afterward Mrs. Fox-Jencken) and one of her sisters gave much of their later lives to acting as mediums in the United States and in England. Many other mediums gave similar sittings, and the movement became widespread. The attempt to communicate with spirits by table turning became a popular pastime in Victorian drawing rooms.

Much of this activity was motivated by mere curiosity and the fascination of the supernatural, but it also had a more serious intention. Many inquirers wished to convince themselves as to human survival of bodily death; others suffered from the loss of loved relatives and friends and found consolation in the belief that they were able to communicate with them; others wanted information about the future life. To promote these serious ends, spiritualist associations or churches were formed.

The rise of this new cult was not allowed to take place without opposition. There was not only verbal condemnation with accusations of fraud but also mob violence. This was, no doubt, partly a popular reaction to a novel system of ideas and practices that were suspected of being based either on fraud or evil. The suspicion of evil was perhaps strengthened by a conjectured relationship to the discarded system of witchcraft. Although individual spiritualists were often members (or even ministers) of Christian churches, the general tendency of the established religious bodies was to suspect the movement and its claim to a new revelation that would either supplement or replace the Christian revelation. The spiritualist practices seemed also to some religious bodies to be a part of the forbidden activity of necromancy. A decree of the Holy Office of the Roman Catholic Church in 1898 condemned spiritistic practices, although permitting legitimate scientific investigation of mediumistic phenomena.

If there was strong and often irrational opposition to spiritualism from the early days of the movement, there was also enthusiastic and often somewhat uncritical acceptance. For those who had lost their faith in traditional Christianity, there was offered a new religion based not on an ancient tradition but on facts that could be observed by anyone. For those to whom materialistic ways of thinking had closed the possibility of a life after death, there was offered a new hope of immortality. To those suffering from grief after the death of their loved ones, there was offered the possibility of communicating with them. There were strong emotional involvements in both the rejection and the acceptance of spiritualism that have made difficult an impartial appraisal of the evidence.

**Assessment.**—From the earliest days, one of the charges against spiritualist mediums was that of fraud—i.e., that they produced their results by the conscious exercise of guessing and trickery—but there does not seem to be any good reason for supposing that this holds for all mediums or for any large number of them. It is, however, clear that the conditions of mediumship are such that it is possible for fraudulent mediumship to be both easy and profitable. Those who attend séances for comfort and reassurance are liable to be uncritical of the evidence offered to them; and a medium using a mixture of guesswork, inference, and items of information such as are likely to apply to most people may mislead the credulous into thinking that they have received information

that could have come only from the departed. A confederate with luminous paint, masks, and cheesecloth may put up a counterfeit series of physical manifestations that also may be accepted by the credulous. Judgment as to the genuineness of phenomena is made more difficult if it is held that a commercial medium may produce a mixture of genuine and counterfeit phenomena. If some mediums are able to produce ectoplasm and ectoplasmic forms, this ability may nevertheless be too sporadic for reliable use, and the medium dependent for his livelihood on the production of spirit forms may use cheesecloth as a supplementary method of satisfying sitters. If a given medium could transmit genuine spirit messages, these too may be sporadic and supplemented by skilful guessing. This supplementation may indeed not be conscious fraud, since the medium may not be aware of whether he is transmitting a spirit message or using his own powers of intelligent guessing.

It is generally agreed that, when fraud is eliminated, there remains a considerable residuum of unevaluated spiritualistic reports, whatever may be their explanation. It does not necessarily follow that the spiritualist explanation must be accepted. Some investigators (e.g., C. Richet) have been strongly convinced of the reality of both mental and physical paranormal phenomena but have considered that they are to be explained without reference to incarnate spirits by scientific principles not yet understood. Richet admitted that what was observed suggested on the surface an explanation in terms of surviving spirits.

Two lines of evidence may be followed to test this type of explanation: first, there is evidence by recognition, when the sitter claims that he has an overwhelming impression of the personality of the communicator (his character, tricks of speech, etc.) as vivid as if he were in his living presence; second, there is evidence by information in which the communicator gives some piece of information that only should have been known to the deceased. The first of these may be convincing to the sitter himself but can be of no value in persuading anyone else. The confirmed skeptic may also be unconvinced by evidence from information or even may deny that it is the result of paranormal cognitive powers (telepathy or clairvoyance) possessed by the medium. (See further *PARAPSYCHOLOGY*.)

In principle, all evidence by information can be explained by postulating sufficient paranormal cognitive capacity in the medium, but to explain claims of evidence for survival in this way would require this kind of explanation to be stretched very far. At least some men have claimed that there is a strong *prima facie* case for some communication from human spirits that have survived death. If, however, there is a genuine element of communication from the departed in some mediumistic utterances, there is also much evidence that such communications can be diluted to an unknown extent, with error supplied by the medium himself or derived from the sitters. To many of those who have thought that they were really in touch with spirits, it has seemed as if they were in touch with them imperfectly and indirectly, as if one were receiving a telephone message not directly but dictated through an operator who understood it imperfectly and added his own glosses as well as transmitting elements of wrong messages. It is possible to hold that mediumistic communications may be of value in providing evidence of life after death without considering that such communications provide reliable information either on the nature of that life or on any other subject.

**SPITALFIELDS**, a district of Stepney in the borough of Tower Hamlets, London, Eng. The land belonged to the rest house or "spital" of St. Mary's Priory (1197), Bishopsgate. Spitalfields Market (6½ ac. [3 ha.], vegetables, fruit, and flowers) was established in 1682. Footwear and furniture are made, and

until about 1900 silk weaving, established by Huguenots after 1685, was important. The Eastertide Spital sermon was given at the pulpit cross in the hospital churchyard until the 17th century.

**SPITHEAD**, an extensive anchorage between the Isle of Wight and the mainland of England, the Spit bank forming the western side of the channel leading to Portsmouth harbour. This anchorage was much used by the Channel fleet in the wars of the 18th century, and is specially suitable for the great naval reviews of modern times. Queen Victoria reviewed the British fleet there in 1853 just before the Crimean War and led the fleet to sea. There was another great naval gathering at Spithead for her funeral in 1901, when her body was conveyed from the Isle of Wight to London. The review by Queen Elizabeth II on her coronation (June 1953) was attended not only by ships of war of many nations, but by every branch of Britain's seafaring industry. (R. N. BA.)

**SPITSBERGEN**: see SVALBARD.

**SPITTA, (JULIUS AUGUST) PHILIPP** (1841–1894), German musician, one of the principal figures in 19th-century musicology. Born at Wechold, Hanover, on Dec. 7, 1841, he studied at Göttingen and later formed a friendship with Brahms. In 1874 he helped found the Bachverein in Leipzig, and the following year he became professor of musical history at the University of Berlin. His *Johann Sebastian Bach* (2 vol., 1873–80; Eng. trans. by C. Bell and J. A. Fuller-Maitland, 3 vol., 1884–85), dealing with Bach's life and religious and technical aspects of his work, was the first comprehensive work on this composer. His editions of the works of Heinrich Schütz and Dietrich Buxtehude established a high standard of scholarship. With Brahms, K. F. F. Chrysander, and others he was one of the chief founders, in 1892, of the great edition of the works of German composers, *Denkmäler deutscher Tonkunst*. He died at Berlin on April 13, 1894.

**SPITTELER, CARL** (1845–1924), Swiss poet of visionary imagination, and author of pessimistic yet heroic verse.

Spitteler was born in Liestal, April 24, 1845. He studied theology in Basel and in Heidelberg and was private tutor for eight years in Russia and Finland. In 1881–82, after his return, his first great work, the mythical epic *Prometheus und Epimetheus* (Eng. trans., 1931), appeared shortly before Nietzsche's *Zarathustra*, a work similar in outlook and in its elevated, quasi-biblical, rhythmical prose style. Alien to the time and strange, it was met with misunderstanding and Spitteler determined "to come down to earth." During the next few years, when he had to make his living by teaching and journalism, he began to express himself in a wide range of literary forms. In 1892 a legacy enabled him to settle in Lucerne and devote himself to creative work. He died there on Dec. 29, 1924.

Spitteler's second great work (which won him the Nobel Prize in 1919) was the poetic epic *Der Olympische Frühling* (1900–05; rev. 1910), in which he found full scope for bold invention and vividly expressive power. The last years of his life were given up to rewriting of his first work. Tauter in composition than the early version and, like *Der Olympische Frühling*, in rhyming couplets, it appeared in 1924 under the title *Prometheus der Dulder*.

The widely varied peripheral works belong to Spitteler's middle period. He produced, in verse, *Extramundana* (1883), seven cosmic myths of his own invention; *Balladen* (1896); *Literarische Gleichnisse* (1892); and two cycles of lyrics, *Schmetterlinge* (1889) and *Gras- und Glockenlieder* (1906). He also wrote two masterly stories—*Die Mädchenfeinde* (1907; Eng. trans., *Two Little Misogynists*, 1922), a childhood idyll derived from his own experience, and *Conrad der Leutnant* (1898), a dramatically finished *Novelle* in which he approached the naturalism he otherwise hated. His novel *Imago* (1906) so sharply reflected his inner conflict between a visionary creative gift and middle-class values that it influenced the development of psychoanalysis. He published a volume of stimulating essays, *Lachende Wahrheiten* (1898; Eng. trans., *Laughing Truths*, 1927), and some biographical works of charm, including *Meine frühesten Erlebnisse* (1914). In 1914 he published a politically influential tract, *Unser Schweizer Standpunkt*, directed against a one-sided pro-German view of the war. An English translation of *Selected Poems* appeared in 1928.

**BIBLIOGRAPHY.**—*Gesammelte Werke*, 11 vol., ed. by G. Bohnenblust, W. Altwegg and R. Faesi (1945–58); *Briefwechsel mit Adolph Frey* (1933). R. Faesi, *Spitteler's Weg und Werk* (1933) and W. Stauffacher, *C. Spitteler's Lyrik* (1950) contain full bibliographical information. See also *C. Spitteler in der Erinnerung seiner Freunde*, ed. by L. Beriger (1947). (R. FA.)

**SPLEEN**, a soft, oblong, purplish organ in the abdomen, is an integral part of the lymphatic and blood vascular systems. Its specially designed lymphatic tissue has the major functions of (1) removing from the blood stream foreign material, including disease-producing organisms and worn-out blood cells; (2) producing lymphocytes and other blood cells; (3) producing antibodies; (4) storing iron and, in some diseases, lipids; and (5) maintaining constant volume of circulating blood. In higher vertebrates the spleen is located in the upper left quadrant of the abdomen just below the diaphragm. It varies in size in different species. Thus, in man, dogs, rats, and mice it approximates 0.25% of the total body weight; in cats and rabbits, 0.05%.

**Microscopic Anatomy.**—The spleen is covered by a contractile capsule composed of dense connective tissue and a few smooth muscle cells. The trabeculae (connective-tissue structures that penetrate the organ) are continuous with the capsule and form a coarse interior scaffolding (see diagram) supporting a finer framework (reticulum) of fixed reticular cells and reticular fibres. The two types of lymphatic tissue, white pulp and red pulp, differ chiefly in the relative number of cell types occurring within the reticulum. White pulp, or dense lymphatic tissue, forms a sheath of varying thickness around the arteries and is reticulum closely packed with lymphocytes. (For detailed descriptions of lymphocytes and other blood and lymph cells mentioned in this article, see BLOOD; LYMPH AND LYMPHATIC SYSTEM.) In the red pulp, or loose lymphatic tissue, the reticulum is pierced in all directions by venous sinuses (see diagram). The reticulum forms the splenic, or Billroth, cords between the sinuses and is filled with lymphocytes, free macrophages (many of which were previously fixed reticular cells), and all circulating blood cells. The venous sinuses contain the same cells but fewer large lymphoid cells and macrophages. The sinuses are lined with flattened reticular cells (littoral cells) and not with true endothelial cells, which line ordinary blood vessels. Arterial blood leaving the smallest branches (arterioles) of the trabecular arteries passes through the cords of the red pulp on its way to the sinuses and out through the trabecular veins. Whether the blood has permanent channels throughout the cords (closed circulation) or simply percolates through temporary passages (open circulation) in the reticulum is not definitely known. Both types of circulation are shown in the diagram.

**Functions.**—As the blood circulates in the spleen, it comes in contact with phagocytes—cells that ingest and destroy other cells, microorganisms, or foreign particles. The most active phagocytes are the fixed reticular cells and free macrophages of the cords; active to a lesser extent are the reticular cells lining the sinuses and free macrophages in the sinuses.

The macrophages of the spleen in the normal animal remove

DIAGRAM OF OUTER PORTION (SECTIONED) OF THE SPLEEN. NOTE THE RELATIONSHIPS OF ARTERY AND VEIN TO THE WHITE AND RED PULP

worn-out or fragmented blood cells and digest them. During this process the iron-containing component of the hemoglobin in the red cells is separated and reutilized by the body. This phagocytic activity may be so great in some blood diseases and infections as to produce anemia. The macrophages also remove foreign matter from the blood, including invading parasites. When the foreign substance is an invading organism or a vaccine containing antigens, the spleen forms antibodies against it. Such antibodies make the bacteria or other particulate antigenic material more readily ingestible by the macrophages. (For a discussion of the mechanism of immunity, see IMMUNITY AND IMMUNIZATION.)

Virulent infections at first generally kill many splenic cells, such as macrophages and especially lymphocytes. Death of lymphocytes results in shrinkage of the white pulp. If the animal survives, lymphocytes and, to a lesser extent, reticular cells proliferate by mitotic division. Some of the new lymphocytes replace those previously lost, and others develop into monocytes and macrophages and probably into antibody-producing cells. Some investigators believe that most of the new macrophages are thus formed from lymphocytes and monocytes and that only a small part arise by the proliferation of reticular cells. The proliferative and developmental processes frequently result in the formation of more splenic tissue, an above-normal number of cells (hyperplasia), and enlargement of the spleen (splenomegaly), which is at times very marked. The extra macrophages in such a spleen are of great functional significance, especially during early stages of infection before antibodies appear.

The spleen is not the only so-called filter organ of the blood. Others are the liver and bone marrow and, to a lesser extent, the adrenal and pituitary glands. The spleen contains the most active macrophages, but the liver, because of its size, can remove as much as 70 times more material. The spleen produces antibodies first in response to antigens in the blood. Its output then falls off, and various nonsplenic sources take over and in time surpass it. The spleen and bone marrow are, among the filter organs, the most important antibody-formers. The liver forms very few antibodies although it is the source of most of the other serum proteins. The spleen, in its blood-cell-forming capacity, produces chiefly lymphocytes, monocytes, and macrophages. The same is true of the lymph nodes and other lymphatic tissue and the bone marrow.

The spleen contains a sizable fraction of the total blood and acts as one of the reservoirs to maintain a constant volume in the general circulation under various conditions.

**Comparative Anatomy and Physiology.**—Knowledge of the physiology of the spleen of the lower vertebrates is largely limited to its role in blood-cell formation. H. E. Jordan believes that the spleen is the fundamental blood-cell-forming organ and that it appeared during the evolution of the vertebrates at about the time of hemoglobin-containing red cells. In the hagfish, among the primitive fish, it is a diffuse tissue; in the lamprey it is a more localized mass of tissue projecting into the dorsal wall of the intestine. In the lungfish it is a discrete organ but is embedded in the stomach. In all the rest of the true fishes and higher vertebrates it is a separate organ located in the dorsal mesentery. In its most primitive form it is the chief site of the formation of red cells, granular leukocytes, and lymphoid cells, but among most higher fishes it has largely lost its ability to produce granular leukocytes and shares the other functions with other tissues. The function of red-blood-cell formation is largely taken over by the red bone marrow in some reptiles and in all higher vertebrates. Although the spleen retains its function of forming lymphocytes, it shares this function with the bone marrow in the reptiles and birds and with bone marrow and lymph nodes in the mammals. It exhibits many of the foregoing capacities, however, in embryonic development or in disease. For example, it forms red cells during a considerable part of human embryonic development. The normal spleen in adult man never forms red cells, but the red pulp in such a disease as myeloid leukemia produces a large number of them, as well as other bone marrow elements. The normal spleen in some animals (e.g., chickens, rats, and mice) probably always forms a few red cells

and may produce enormous numbers of them in certain infections, such as malaria

**BIBLIOGRAPHY.**—H. E. Jordan, "Comparative Hematology," in Hal Downey (ed.), *Handbook of Hematology*, vol. ii (1938); Aleksandr A. Maksimov and William Bloom, *A Textbook of Histology*, 7th ed. (1957); William H. Taliaferro, "Functions of the Spleen in Immunity," *Am. J. Trop. Med.* 3:391-410 (1956). (W. H. T.; X.)

**SPLEEN, DISEASES OF.** The diseases of the spleen (*q.v.*), which are numerous, depend in large measure upon the peculiarities of that organ. The spleen has no outstanding function, yet it has many rather subtle functions. It may be removed with impunity, yet it contributes to the development of immune responses. It is ordinarily useful, yet it may become harmful to the body, particularly when enlarged. In some ways the spleen is a sponge or reservoir containing excess blood; in other respects it is like a large lymph gland situated within the abdominal (portal) circulation; it has many phagocytic cells designed to capture particles and debris.

The spleen may become enlarged (splenomegaly) for a variety of reasons: reaction to certain infections or to immune processes; congestion with excess blood as in polycythemia or in cirrhosis of the liver; stuffing with abnormal cells, as in Gaucher's disease, leukemia or a related disease called myeloid metaplasia. Certain tumours begin in the spleen (lymphosarcoma); peculiarly, ordinary cancers are usually unable to gain a foothold in that organ.

The spleen, being part of the lymphoid apparatus, becomes enlarged in diseases involving this system, as in lymphocytic leukemia and infectious mononucleosis. As part of the reticulo-endothelial system, it becomes enlarged when this phagocytic system is overactive as in tuberculosis, rheumatoid arthritis and histoplasmosis. The spleen is easily distensible, so that when the portal circulation is filled with stagnant blood under great pressure due to inability of blood to go through the liver, it takes up extra blood and becomes congested.

In many cases, enlargement of the spleen is accompanied by a reduction in the cells of the blood; thus either the red cells may be affected (anemia), or the white cells (leukopenia) or the platelets (thrombocytopenia). Involvement of all three blood elements is called pancytopenia, and this occurs fairly commonly in hypersplenism, the term given to reductions in blood elements associated with enlargement of the spleen. Sometimes the hypersplenic state is so striking and the blood counts so low that it is desirable to remove the spleen. The spleen also may be removed in certain cases of blood destruction (hemolytic anemia) and blood platelet reduction (thrombocytopenic purpura); however, in these cases all other avenues of treatment, notably the use of cortisone preparations, should be explored first. In one condition, hereditary spherocytosis or congenital hemolytic jaundice, removal of the spleen results in complete cure of the anemia. Here the spleen itself is normal, but the bone marrow produces spherocytes which are actually trapped by the spleen. Removing the spleen removes the trap and cures the condition. In certain tumours and cysts of the spleen it is best to remove the organ, especially since modern surgery allows removal without much reaction. Certain cases of leukemia with large spleens are treated with various chemicals, others by high-voltage X-rays.

(W. Dk.)

**SPLIT** (Italian SPALATO), a city and seaport of the Socialist Republic of Croatia, Yugos., has the finest harbour on the Adriatic coast, with a broad bay affording deep, safe anchorage. This, combined with its central position on the coast and its good communications with northern parts of Yugoslavia by rail, has made it of great commercial importance, with an extensive trade in cement, timber, and marble. The projected direct rail communication with Bosnia will further increase the value of Split as a port. Pop. (1961) 99,462, almost entirely Croatian.

The old town is built within the palace of Diocletian, who renounced the imperial crown in A.D. 305 and lived there till his death (probably 313). The palace was built from 295 to 305, with the walls 7 ft. (2 m.) thick and 72 ft. (22 m.) high on its seaward side and 60 ft. (18 m.) high on the northern side. It has 16 towers and 4 gates: Porta Aurea (north), Porta Argentea (east), Porta Ferrea (west), and Porta Aenea (south). The Avars

damaged this palace, but when their incursion was over (639), the inhabitants of the ruined city of Salona (Salonae) nearby took refuge there and built their homes within the 9½ ac. (4 ha.) covered by the palace, incorporating its walls and pillars. Its ground plan is like a Roman camp; i.e., rectangular with 4 streets meeting in the middle. The streets are lined with massive arcades. The mausoleum of Diocletian has since the 7th century been a cathedral and is noteworthy for its finely carved choir stalls. The Temple of Jupiter, or Asclepius, has been long transformed into a baptistery, a beautiful Romanesque campanile having been added in the 14th and 15th centuries. In the old part of the town are the palaces Cindro, Ivello, and Papalić, and the house in which was born the medieval Slav poet Marko Marulić. Near the Porta Aurea is the huge and notable statue of Bishop Gregory of Nin by the Croatian sculptor Ivan Mestrovic.

From 812 Split was under Byzantine rule, and in 1069 it fell to Croatia. After 1075 it passed under a series of masters, the Normans, Venice, Byzantium again, Hungarian-Croat kings, Bosnian rulers, and then, from 1420 till 1797, Venice. The Austrians ruled from 1797 till 1918 when Yugoslavia was formed. In 1941 Italian forces occupied the city. In September 1943 the First Partisan Brigade together with Dalmatian brigades liberated Split, but under heavy pressure from German forces the Partisans withdrew. From 1945 Split again became part of Yugoslavia.

Excavations have been carried on intermittently at the ruins of Salona, 4 mi. (6 km.) NE of Split, since 1818, and many interesting architectural remains have been discovered, together with many smaller relics now housed in the Split museum. These include prehistoric objects. Salona was made a Roman colony in 78 B.C. and was one of the chief ports of the Adriatic. Soon after 313 the city became an episcopal see, with St. Doimo as its first bishop. The palace was transformed into an imperial cloth factory. The town was captured several times by the Goths and Huns and in 639 was destroyed by the Avars, but it was not entirely deserted until the end of the 12th century. (V. DE.)

**SPLÜGEN PASS**, a pass (6,932 ft. [2,113 m.]) across the east-west range of the Ticino Alps on the Swiss-Italian frontier. The Splügen route runs south from Thusis in the Hinterrhein Valley through the defile of the Via Mala, crossed by medieval bridges at two levels until a new road was completed through a rock tunnel at a higher level. It then crosses the Schams Basin and continues west via the Rofna Gorge, past the recent Stufers barrage, to Splügen village. The road to the pass (completed 1822) leaves the San Bernardino Pass road, turning south to cross the Splügen Pass (Passo dello Spluga), then continues past the modern lake reservoir of Montespluga down the steep descent into Italy. The new road avoids the old track along the avalanche-prone Cardinello Gorge above Pianazzo, where many men of Alexandre Macdonald's army perished in 1800. Continuing south through Campodolcino, the road joins that from the Upper Engadine and the Maloja Pass at Chiavenna (railhead of the Mera Valley) and then continues south along Lake Como to Como.

(A. F. A. M.)

**SPODUMENE**, a variety of pyroxene (*q.v.*) consisting of lithium aluminum silicate, is an important ore of lithium and source of ceramic materials. It was named in 1800 from the Greek word meaning "ash coloured," and soon afterward termed by the crystallographer R. J. Haüy, triphane ("appearing threefold") because it exhibited certain characteristics equally in three directions. The hardness is 6.5 to 7 and though generally a dull mineral, some varieties are so highly coloured and transparent as to be valued as gem stones, e.g., the emerald-green hiddenite and the lilac-coloured kunzite, while a yellow or yellowish-green spodumene found as pebbles in Minas Gerais, Braz., resembles, when cut, some kinds of chrysoberyl. The largest natural crystals are found in pegmatite dikes in the United States in Massachusetts, Connecticut, and the Black Hills of South Dakota. Canada is an important primary producer of spodumene ore and concentrates. Chloride volatilization, alkaline leaching, and acid leaching are used to extract lithium from the ore prior to the manufacture of purified lithium chemicals. (For production and uses of compounds and the metal, see LITHIUM.)

Spodumene,  $\text{LiAl}(\text{SiO}_3)_2$  or  $\text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$ , exists in nature as a dense (specific gravity 3.2)  $\alpha$  form and changes on heating at  $1,000^\circ\text{C}$  to a much less dense (specific gravity 2.4)  $\beta$  form with a different crystal structure than the natural mineral. The large specific gravity change is used in the beneficiation procedure known as the "decrepitation" process since the rocklike mineral shatters to small particles when it is heated rapidly to temperatures above  $1,000^\circ\text{C}$ , facilitating the separation of accessory mineral impurities. This high temperature form has an extremely low thermal expansion, making it a very important thermal shock-resisting ceramic material. In minor amounts, spodumene is used in glass, enamels, and glazes. (F. A. HL.)

**SPOHR, LOUIS** (1784–1859), German composer, conductor, and violinist, who had great influence as a violin teacher and whose compositions illustrate the beginning of the Romantic period in German music. Born at Brunswick on April 5, 1784, he was largely self taught, acquiring his knowledge of composition from study of the scores of Mozart. At Brunswick he took violin lessons from the leader of the Brunswick orchestra and was appointed chamber musician there in 1799. In 1802 he studied with a pupil of J. W. A. Stamitz, Franz Eck, who took him on a tour to Russia. He made the first of his tours in Germany as a violinist and composer in 1804, and two years later he married the harp virtuoso Dorette Scheidler (1787–1834), with whom he toured during the following three years. While he was *Kapellmeister* in Vienna, at the Theater an der Wien (1812–15), he came under the influence of the French violinist Pierre Rode, a pupil of G. B. Viotti. Later he toured Italy with Paganini and in 1817 was appointed conductor at Frankfurt am Main. In 1820 he made the first of his six tours of England. The following year Weber recommended him to the court at Kassel, where he was appointed conductor in 1822. In 1836, after the death of his first wife, he married the pianist Marianne Pfeiffer (1807–92). In his later years Spohr suffered from the despotism of his patron, the elector of Hesse-Kassel, who pensioned him in 1857. Shortly afterward he broke his left arm and was no longer able to play the violin. He died at Kassel on Oct. 22, 1859.

As a teacher of the violin, Spohr carried into the 19th century the traditions of Stamitz and Viotti. His method was set out in his *Violinschule* (1831). Though opposed to the forward-looking composers of his time—he failed to appreciate the works of Weber and those of Beethoven's last period—he nonetheless conducted 2 works of Wagner, *The Flying Dutchman* and *Tannhäuser*, at Kassel, despite great opposition. He was a prolific composer, the style of his works, predominantly in the minor key, having some kinship with that of Schubert and Mendelssohn. Of his 10 operas, *Faust* (Prague, 1816), together with E. T. A. Hoffmann's *Undine*, was the first of the German romantic operas; his *Jessonda* (Kassel, 1823) held the stage throughout the 19th century. Of his 9 symphonies, the fourth, *Die Weihe der Töne* ("The Consecration of Sound"), was the most successful and was revived in the 20th century. The best known of his 15 violin concertos is the eighth, in A minor, written for his Italian tour. His chamber works include 34 string quartets, 4 double string quartets, and the well-known nonet. A selection of his works was published from 1949 onward at Kassel, where in 1954 the Spohr-Gesellschaft was founded.

**BIBLIOGRAPHY.**—*Louis Spohr's Autobiography*, 2 vol., Eng. trans. (1865); F. Goethel, *Das Violinspiel L. Spohrs* (1935); E. E. L. H. Salburg-Falkenstein, *Ludwig Spohr* (1936).

**SPOIL FIVE**, once known as the national card game of Ireland, is akin to the British napoleon, the American euchre and the French écarté (*qq.v.*). Spoil five and its variant, forty-five, were carried to the United States and Canada, while the variant auction forty-fives, introduced into Newfoundland in 1912, became the principal club game there. Spoil five is much like loo (*q.v.*). A pool is formed by equal antes. Each player receives five cards and the next card is turned up for trump. Anyone who wins three tricks must take the pool or jink it (play for all five tricks for the pool plus an extra chip from each player). The hand is spoiled if no one wins the pool, which then is added to the next pool.

The ace of hearts is always the third-best trump, whatever the

trump suit. Above it are the five and jack (knave) of trumps; below it, the ace, king, queen. In the red suits the lower cards rank normally: 10 (high), 9, 8 . . . and so on, but in the black suits the rank is reversed: 2 (high), 3, 4 . . . 10 (low). When not trump the spade and club aces rank below the jack, and the diamond ace ranks below the 2.

**Forty-Five.**—This is a variant in which there is no pool; four or six play, in partnerships of two or three to a side. A side winning three tricks scores 5 points; all five tricks, 10 points. As some play, winning four tricks scores 15 points and all five tricks 25 points. The first side to reach 45 points wins.

In auction forty-fives trump and contract are determined by bidding. Each trick counts 5 and the highest trump an additional 5; game is 120. (G. M.H.)

**SPOILS SYSTEM**, the practice, also known as the patronage system, under which, in the United States, the political party winning an election rewards its campaign workers and other active supporters by appointment to public office. It involves political activity by public employees in support of their party and removal from office if their party loses the election. A change in party control of government necessarily brings new officials to high positions carrying political responsibility, but the spoils system extends personnel turnover down to routine or subordinate governmental positions. In the most extreme form of the spoils system the primary test for appointment is excellence of party service, with almost complete disregard of capacity to perform the duties of the public office concerned. The term apparently originated with a speech made in 1832 by Sen. W. L. Marcy in which he asserted that, "to the victor belong the spoils of the enemy."

The term is often applied loosely to the great variety of means by which money may be transferred more or less indirectly from the public treasury to the party coffers, as well as to other abuses of governmental power for partisan advantage. So used, the term includes abuses in the management of public expenditures, irregularities in the granting of franchises and other privileges, partisan favoritism in the administration of criminal law, discrimination in the levy of taxes, and other corrupt uses of public power. The term will be limited here to its earlier and narrower usage.

Although patronage existed in colonial times, the spoils system came to full bloom in the period 1800-29. When Jefferson became president in 1801, he found the public offices filled with persons generally hostile to him and to his party. Without espousing the principle of rotation in office, he replaced enough Federalists with Republicans (as Jefferson's followers were then called) to assure a more even distribution between the two parties in the civil service. Yet in both appointments and removals partisan considerations were not the sole criterion; it remained for President Jackson to introduce the principle of the spoils system in the national government, yet even Jackson did not make wholesale removals on political grounds. Spoils practices had been instituted earlier in the governments of states and cities. The system first became firmly rooted in New York; it was established almost as soon in Pennsylvania. By 1828 in all the states of the north and west the system existed or strong groups desired to introduce it.

In his annual message in 1829 Jackson presented a reasoned philosophy of the spoils system. "There are," he said, "perhaps few men who can for any great length of time enjoy office without being more or less under the influence of feelings unfavourable to the faithful discharge of their public duties. Their integrity may be proof against improper considerations immediately addressed to themselves, but they are apt to acquire a habit of looking with indifference upon the public interests and of tolerating conduct from which an unpracticed man would revolt." Rotation in office, then, was not an evil but a positive good. "The duties of all public offices are," he declared, "or at least admit of being made, so plain and simple that men of intelligence may readily qualify themselves for their performance; and I cannot but believe that more is lost by the long continuance of men in office than is generally to be gained by their experience."

The common explanation of the rise of the spoils system is that ways had to be found to support the activities of political

parties. With the broadening of the suffrage, the use of elections to choose large numbers of officials, and other tendencies toward democratization, political parties had to assume heavy burdens in the conduct of campaigns and leadership of debate on public issues. As no class existed with the time or inclination to assume these responsibilities, parties had to be maintained by patronage. Practical considerations of party finance were reinforced by a democratic dislike of the idea of public office as private property and a hostility toward the rise of an officeholding class.

The spoils system is often said to be peculiar to the United States, but similar practices have existed elsewhere from time to time. In fact, the distribution of public offices to strengthen a regime is an ancient practice of statecraft. At the time of the founding of the United States government, the tests for appointment to the civil service were probity, ability, and loyalty to the Constitution. The test of loyalty aided in buttressing a new government emerging from controversy. The installation of Fascist dictatorships in Germany and Italy in the first half of the 20th century was accompanied by considerable partisan dilution of the permanent civil service. If the nature of a government changes radically, a degree of turnover in the civil service is likely to occur. The introduction of the spoils system into the national government of the United States coincided with a veritable revolution as new classes came to power in national affairs. Even systems for the selection of public employees on the basis of merit may, in fact, reserve the higher positions for members of the dominant groups within the community.

The spoils system flourished unchallenged in the United States until after the Civil War. Bills to reform the civil service were introduced in Congress in the 1860s, but they attracted little attention and less support. In 1871 Congress empowered the president to prescribe regulations to govern the selection of civil servants and to employ persons to aid him in determining the fitness of applicants. President Grant appointed a Civil Service Commission, but it was dissolved in 1875 after Congress had failed in 1873 and 1874 to provide funds for its support.

The National Civil Service Reform League, established in 1881, led a reform movement that succeeded gradually in restricting the spoils system by the introduction of the merit system for the selection of civil servants. The movement gained impetus from the assassination of President Garfield by a disappointed office seeker, and in 1883, the Pendleton Act, largely drafted by leaders of the Reform League, was adopted by Congress. It provided for the creation of the United States Civil Service Commission and for the merit system in the recruitment of some federal civil servants. In the same year New York adopted a civil service law requiring the selection of civil employees through competitive examination. After 1939, all states were compelled to institute merit systems for employees engaged in programs aided by federal subsidies.

In the second half of the 20th century about 75% of the U.S. cities had established some type of formal merit system. However, only 25% of the cities covered all employees, and almost half of those reporting cities with a population of less than 25,000 had established no formal civil service system. As the merit system encroached on the spoils system in state and local governments, its application was broadened in the national government by actions of various presidents. A setback to the merit principle occurred after World Wars I and II in the extension to war veterans of preference in appointments.

The coverage of civil service legislation, however, does not indicate accurately the extent to which the spoils system has been superseded. In jurisdictions with civil service laws, spoils practices may prevail. In those lacking formal merit systems, ability may govern selection of employees, and their tenure may be permanent. See CIVIL SERVICE. (V. O. K.; X.)

**SPOKANE**, a city of eastern Washington, U.S., the county seat of Spokane county, is situated on the high river plain of the Spokane river about 50 mi. from its juncture with the Columbia, at an altitude of 1,898 ft. To the north and east lie the Selkirk and Rocky mountains, generally shielding the valley from the rigours of northeast winds which on occasion cause spells of ex-

treme cold. The population of the city in 1960 was 181,608 and of its standard metropolitan statistical area (Spokane county), 278,333. For comparative population figures see table in WASHINGTON: *Population*.

Only five years after the notable Lewis and Clark expedition of 1804–06, the first white habitation of the Pacific northwest, Spokane House, a North-West Fur company post, was built on the Little Spokane river. Ft. Spokane, an Astor establishment, was built across the river from its competitor. When the Hudson's Bay company, successor to the North-West company, moved its operation to Ft. Colville in 1826, that settlement eclipsed the Spokane country. During the missionary period, the Indian disturbances and the early mining boom, Walla Walla held the stage. It was not until 1872 that a settlement was established at Spokane Falls. A village by that name was incorporated in 1881 and the following year it was chartered and also replaced Cheney as the county seat.

In 1880 the town's population was only 350. With the advent of the Northern Pacific railroad in 1883, however, it mushroomed, and by 1890 it had outstripped Walla Walla and enjoyed third rank in the state. With a revival of mining in the 1880s, this time of the more stable lode-mining type, Spokane became the region's financial and mercantile focal point. In 1886 it had an electric-light plant and a horse streetcar line. An electric trolley system in operation by 1891 served the city until 1935. Additional rail facilities, particularly the Union Pacific (1889) and the Great Northern (1892), and a number of branch feeder lines contributed to Spokane's ultimately becoming the largest railroad centre west of Omaha. From the holocaust of Aug. 4–6, 1889, when 30 blocks in the middle of the city were destroyed by fire, there emerged a more modern city.

The word "Falls" was dropped from the name in 1890. The word Spokane, said to mean "children of the sun," was the name of an Indian tribe which had formerly occupied the valley. It is pronounced to rhyme with "man."

There are three private institutions of collegiate rank: Gonzaga, a coeducational Roman Catholic university founded in 1887; Whitworth, a Presbyterian coeducational college established in 1890; and Holy Names, a Roman Catholic college for women, incorporated in 1907.

The Fox theatre, the Spokane coliseum and the municipal stadium have been the settings for a great variety of entertainment. The city has a symphony and a junior symphony orchestra.

Diversity is the keynote of the city's economy, to which agriculture, mining, lumbering, processing of primary metals, general manufacturing and distribution contribute. An abundance of cheap hydroelectric power has been a major stimulus and was particularly instrumental in the establishment during World War II of the aluminum reduction mill at Mead and the aluminum rolling mill at Trentwood. In 1954 two large oil pipelines reached the city and natural gas was made available in 1956.

The city owns Geiger field serving commercial airlines and Felts field, which serves principally private planes. (H. J. DE.)

**SPOLETO** (ancient **SPOLETIUM**), a town and archiepiscopal see of the province of Perugia, Italy, 18 mi. (29 km.) NNE of Terni and 88 mi. (142 km.) N of Rome by rail. Pop. (1961) 38,563 (commune). Finely situated on a detached spur at the southern extremity of the central Umbrian Plain, it commands the passes southward toward Terni and eastward toward Norcia and the upper valley of the Nera. The old town clusters picturesquely on the hillside; modern development is largely confined to the plain below.

The most conspicuous remains of the ancient town are the walls of polygonal masonry, partly of the pre-Roman city and partly of the Roman *colonia*. The Piazza del Mercato occupies the site of the Roman Forum, with an arch of Drusus and Germanicus (A.D. 23), and beside it the remains of a temple. Other surviving Roman monuments are a theatre, an amphitheatre, a house with mosaics, and a three-arched bridge. From a circular tumulus found in 1902 at Monteleone di Spoleto comes the famous biga (two-horse chariot), a remarkable example of 6th-century B.C. bronze work, now in the Metropolitan Museum, New York.

The medieval town is dominated by the massive Rocca, built by Matteo Gattapone for Cardinal Alborno in 1364 on the site of the ancient citadel. Just below stands the cathedral, which was consecrated in 1198 and extensively remodeled in 1634. Above the graceful Early Renaissance vestibule the facade, with its eight rose windows, and central mosaic by Solsternus (1207), is that of the 12th-century building. The interior is dominated by a magnificent fresco of the Coronation of the Virgin by Fra Filippo Lippi and pupils; Lippi's tomb, erected by Lorenzo de' Medici, is in the south transept.

The many other fine churches include Sta. Eufemia (10th century); S. Pietro (about 1200), with a richly sculptured facade; SS. Giovanni e Paolo, the paintings of which include early representations of the martyrdom of St. Thomas Becket and of St. Francis; and S. Domenico and S. Niccolò, characteristic examples of late Italian Gothic. The church of S. Salvatore is an elaborately decorated, classicizing monument, usually assigned to the 5th century but possibly dating from the late 8th century. The city is supplied with water by an aqueduct that crosses the ravine upon a bridge of ten arches built in 1364. A garrison town and the centre of a large agricultural district (predominantly olive culture), Spoleto has also developed a certain number of light industries (cotton goods, phosphorus products, printing). Since 1958 it has had an annual drama and music festival.

The site of an Umbrian township from at least the 7th to 6th centuries B.C., Spoleto became a Latin colony in 241. In 217 B.C. it successfully repulsed Hannibal, fresh from his victory on Lago Trasimeno. Strategically situated on the Via Flaminia, its importance increased in late antiquity. It became an episcopal see not later than the early 4th century, and it played an important part in the Gothic wars of Belisarius and Narses. With the foundation of the Lombard duchy about 570, it became for several centuries one of the principal cities of Italy, for a time sharing with Benevento the rule of much of the peninsula. After the middle of the 8th century, however, the duchy lost much of its autonomy, and under Gregory IX (pope 1227–41) it passed to the church. During the absence of the papal court in Avignon, it was a prey to struggles between Guelphs and Ghibellines, until in 1354 Cardinal Alborno reestablished the authority of the church, under which it remained, except for brief intervals, until captured by the Italian troops in 1860. (J. B. W.-P.)

**SPONGE**, an aquatic animal characterized by a unique organization. Sponges, which constitute the phylum Porifera, number approximately 5,000 described species and inhabit all seas, where they occur attached to surfaces from the intertidal zone to depths of 8,500 m. or more. Only one family, the Spongillidae, is found in fresh water.

Early naturalists regarded the sponges as plants because of their frequent branching form and their lack of obvious movement. Ellis first clearly described the animal nature of sponges in 1755, and in 1765 reported his observations of their water currents and the movement of their openings. Although many zoologists regard the sponges as occupying an isolated position in the animal king-

FIG. 1.—LIVING BATH SPONGE PULLED FROM ITS ATTACHMENT ON THE SEA BOTTOM AND SLICED IN HALF

dom and classify them in the subkingdom Parazoa, or Enantiozoa, others present arguments for relating them rather closely to the coelenterates.

### GENERAL FEATURES

**Importance.**—The bath sponge in its living state is a mass of cells and fibres. Its interior is permeated by an intricate system of canals that open out as holes of various sizes through the tough dark-brown or black skin. The skin may be hairy from the fibre endings that pierce it. Only when it is completely cleaned of its millions of living cells does the bath sponge look like the sponge of commerce, the spongin skeletal framework that serves a variety of uses. These soft elastic sponges, derived from certain species of Demospongiae (*Spongia* and *Hippospongia*), have been known since ancient times. They were familiar household items in ancient Greece and Rome, where they were used for applying paint, as mops, and by soldiers as substitutes for drinking vessels. During the Middle Ages, burnt sponge was reputed to have therapeutic value in the treatment of various diseases.

In the present day, synthetic plastic sponges have largely replaced natural ones for household use, but there is still a demand for natural sponges by various artisans and for surgical use. Commercially valuable sponges are harvested in the eastern Mediterranean, off the west coast of Florida and the Florida Keys, in the West Indies, off Mexico and British Honduras, and, to a limited extent, off the Philippines. The most valuable sponges are found in the eastern Mediterranean.

Commercial sponges are gathered from tidal level to a depth of about 200 ft. In shallow waters they are harvested by hooking or harpooning from a boat. Skin divers exploit cave populations in the Aegean Sea and along the Libyan coast and in the Philippines. Deepwater fishing in Florida, Greece, and North Africa is accomplished with the aid of diving suits. Dredging, a wasteful method, has been used in Libya but is prohibited in the Western Hemisphere. Preparation of sponges, done aboard the boat or along the shore, consists of rotting away and expressing the soft tissues, rinsing in seawater, and air drying. Certain grades of sponges are bleached before marketing.

**Form and Colour.**—Sponges vary considerably in external appearance, colour, and size. The main growth patterns are irregularly massive, branching, and encrusting, but symmetrical shapes, as spherical and lenticular, also occur. In size, sponges range from urns only a fraction of an inch long to upright vases, tubes, and branching types up to eight feet tall and broad rounded masses several feet in diameter.

Sponges, especially those growing in shallow tropical waters, are characterized by more or less irregular shapes and bright colours. They may be various shades of blue, violet, magenta, red, orange, yellow, green, brown, tan, gray, black, and white. Deep-sea species tend to be more regular in shape and more sombre in hue, usually some shade of brown, tan, cream, gray, or white. Not infrequently the same species occurs in several forms and colour phases. Freshwater sponges are irregular masses, chiefly gray, brown, tan, or white, but at least one species is bright yellow. Many freshwater sponges and some shallow-water marine species have algae or bacteria living in their cells; these organisms impart their colour to the sponges.

### STRUCTURE AND FUNCTION

A sponge is a filter-feeding animal that propels water through a system of channels in its body and feeds upon the minute or-

ganisms and particles carried in with the currents. Sponges are covered by an outer dermal membrane perforated with pores that allow water to enter. The motile power for the water currents within the sponge is provided by the coordinated whipping action of flagella on collar cells (choanocytes) grouped in the interior of the sponge. Between the dermal membrane and the choanocytes are mesenchyme cells of several sorts, some of which secrete supporting fibres of protein or spicules of calcium carbonate or silicon dioxide.

**Grades of Construction.**—Three basic grades of construction of increasing complexity may be recognized among sponges: ascon, sycon, and leucon. The simplest, or ascon, type is exemplified by the calcareous sponge genus *Leucosolenia*, which consists of colonies of upright hollow tubules. Each tubule has an external dermal membrane perforated at intervals by pores, actually openings through cells, called porocytes. The hollow interior is lined with choanocytes, the beating of the flagella of which draws water through the pores and forces it out a single large opening (osculum) at the apex of the tubule. Between the dermal membrane and the choanocytes lies a layer of mesogloea, a colloidal gel, in which lie mesenchymal cells and spicules.

A somewhat more complicated construction is the sycon type, as seen in the calcareous sponge genus *Sycon*. Here the wall of the sponge is pushed out into fingerlike projections, called radial canals, each provided with a lining of choanocytes. Water enters the radial canals directly through pores, makes its way into the central cavity or spongocoel, and leaves by way of a terminal osculum. In some *Calcarea* a cortex consisting of the dermal membrane and mesenchymal cells covers the outer ends of the radial canals, and water entering through dermal pores courses through incurrent channels in the cortex before reaching the radial canals.

All adult Demospongiae and many *Calcarea* are of the complicated leucon structure. In the *Calcarea* this grade of construction has evolved through a subdivision of the radial canals into numerous small flagellated chambers in which the choanocytes are localized. These chambers communicate with the dermal pores by way of incurrent canals and with the spongocoel by way of excurrent canals. In some *Calcarea* the leuconoid stage has apparently resulted from the union of asconoid tubules.

**Cell Types.**—The cells of sponges exhibit considerable diversity and functional specialization. The various sorts are defined with regard to their size, nuclear characteristics, cytoplasmic inclusions, and the nature of the pseudopodia, if present. It is often difficult to relate the cell types from one species of sponge to another, and the literature on sponges is somewhat confusing because of the variety of names used by different authors for what are apparently homologous cells. In the adult sponge the cells can be divided into nucleolate and anucleolate sorts. The former include unspecialized archaeocytes, amoebocytes of several types, scleroblasts, or spicule cells, and presumptive egg cells; the latter

FIG. 3.—DIAGRAM OF VARIOUS TYPES OF SPONGE ORGANIZATION (CHOANO-CYTE LAYER IS BLACK; MESENCHYME LAYER IS GRAY; SMALL ARROWS INDICATE DIRECTION OF WATER FLOW)

include pinacocytes, collencytes, and choanocytes.

The archaeocytes found in the adult sponge tend to be ovoid in shape and have nucleoli and a small number of cytoplasmic inclusions. In the adult sponge they continue to give rise to scleroblasts and germ cells, but whether they can transform into all other types of cells throughout the life of the sponge, as is sometimes held, is still unsettled. The amoebocytes, which possess lobose pseudopodia, can perform a variety of functions, according to which they are often given special names: chromocytes, if they bear pigment granules or symbiotic algae; thesocytes or spherular cells, if they are filled with food reserves; or trophocytes, if they are acting as nutritive cells for developing eggs. Amoebocytes are probably also the source of mucus-secreting gland cells that occur commonly in sponges.

Pinacocytes are flattened polygonal cells that make up the external epithelium of sponges and also line the excurrent canals. Those on the exterior (exopinacocytes) lack nucleoli, whereas those lining the canals (endopinacocytes) are nucleolate. Pinacocytes may be differentiated into myocytes, spindle-shaped contractile cells that occur in circlets under the epithelium around incurrent and excurrent openings. Collencytes have been described as "internal pinacocytes"; they are star shaped, with long, thin processes that insinuate throughout the incurrent canals of the sponge. Certain collencytes, called desmacytes, or fibre cells, are found in abundance in the cortex of some species of sponges. Star-shaped collencytes with a vesicular or vacuolate structure are called cystocytes.

Choanocytes, the most highly differentiated cells in the sponge body, are also the smallest cells, exclusive of sperm. The cell body is provided with a single flagellum surrounded by a collar made up of a circlet of cytoplasmic tentacles. The flagellum of the choanocyte is consistent in basic structure with the flagella and cilia of other animals, being composed of two centrally placed fibres surrounded by a circlet of nine double fibres continuous with the basal body.

There is cytological evidence for the existence of bipolar and multipolar nerve cells in a wide variety of Calcarea and Demospongiae. Unequivocal proof that these cells do indeed have a nervous function can be supplied only by physiological techniques, however. Peculiar cells called lophocytes, which bear tufts of fibrillae, have been described in freshwater sponges and in certain marine Demospongiae. In spongillids they occur between a double layer of pinacocytes on the surface of the sponge, and in marine sponges they occur in tracts of mesenchyme near the surface. Lophocytes have been interpreted either as nervous elements or, more probably, as cells that secrete fibrils characteristic of the cortical mesenchyme of sponges.

FIG. 4.—TYPES OF SPONGE CELLS

A hyaline ground substance, bearing fine collagenous fibres, surrounds the mesenchymal cells and spicules of sponges. In simple, tubular calcareous sponges the mesogloea is secreted by choanocytes or amoebocytes. The substance stiffens into a firm colloidal gel around the spicules and is capable of supporting the oscular tube after dissolution of the spicules.

**Water Current System.**—Spongillids consist of two discrete canal systems, an incurrent and an excurrent system, joined by

way of numerous flagellated chambers. The external, or dermal, membrane of the sponge, composed of pinacocytes, is perforated by ostia through which water enters the incurrent canal system, usually by way of large subdermal cavities. Pinacocytes also line the excurrent canals. The incurrent canals are not so lined but instead are filled with a network of free cells, including collencytes, archaeocytes, and amoebocytes.

The choanocytes are localized in hemispherical chambers with a diameter of 40 to 60  $\mu$ . These chambers lie between the incurrent and excurrent canal systems, and water must pass through them in flowing from the incurrent canals into the excurrent canals. Two or three openings, called prosopyles, which are apparently simply spaces between choanocytes, lead into each flagellated chamber. A single larger opening, the apopyle, permits water in the chamber to flow into an excurrent canal. The excurrent canals converge on one or more openings to the outside, the oscules, surrounded by contractile myocytes that regulate the size of the opening.

The uncoordinated beating of the flagella of the choanocytes creates the flow of water through the sponge. With the collar expanded, four to six undulations can be seen in the flagellum as it beats. The rotating movement of numerous adjacent flagella in the chamber probably creates eddy currents that help to direct food particles against the collar. When the collar is contracted, as is true when choanocytes are isolated, the flagellum beats backward and forward in a manner and frequency analogous to the beating of a cilium of *Paramecium*.

In living cultures the collars of the choanocytes lining a flagellated chamber are oriented so that each directs the current created by the flagellum toward the apopyle. This opening is ten times larger than the diameters of all of the prosopyles leading into any one chamber, so that water enters a chamber with a velocity ten times greater than it leaves. The sudden slowing of the velocity of the current in the chamber probably facilitates food gathering. As a result of the fall in pressure in the chambers, the prosopyles exert a suction effect on the water in the incurrent canals and subdermal cavities, and water carrying food particles is drawn forcibly through the ostia from the external medium. The network of cells filling the incurrent canals exerts a frictional drag on the water, but this slowing effect is counterbalanced by the tendency for water to flow more rapidly through spaces of smaller diameter. The velocity of current flow is twice as great in the incurrent canals as in the excurrent canals, which have a smooth lining of pinacocytes but are also larger in diameter. The pumping action of the flagellated chambers combined with the changing size of the oscular orifice leads to an excess pressure in the excurrent canals and thus water, free of food, low in oxygen, and carrying excretory products, flows some distance from the sponge and is unlikely to reenter through the incurrent openings.

Some data exist on the amount and velocity of water filtered by marine sponges. In a tubular calcareous sponge, *Leuconia*, with a height of 9 cm. and a diameter of 1 cm., the combined activity of all flagella in the sponge was found to be sufficient to force a jet of water, moving at a rate of 8.5 cm. per sec., a distance of 23 cm. beyond the osculum at a pumping rate of 22.7 litres per day. A single tubular branch of *Callyspongia vaginalis*, 10 cm. high and 4 cm. in diameter, can discharge 78 litres of water per day through its oscule. A young spongillid with a volume of 0.2 mm<sup>3</sup> can discharge 4.5 cm<sup>3</sup> of water per day, each flagellated chamber pumping 1,200 times its volume of water per day.

In the marine siliceous sponge *Hymeniacidon heliophila*, the oscules close in quiet seawater, when exposed to air, on injury to adjacent parts, and in deoxygenated seawater. Partial closing occurs in dilute seawater and at temperatures between 35° and 45° C. The oscules remain open in currents of seawater and are apparently unaffected by low temperatures and light. The ostia close on injury to adjacent parts but remain open in quiet seawater, upon exposure to air, in deoxygenated seawater, and in seawater at 35° C. Partial closing occurs in dilute seawater, and ostia are unaffected by low temperatures and light. Closing of both oscules and ostia is brought about by the contraction of myocytes arranged as sphincters around the openings. Myocytes serve to regulate the rate of flow of water, helping the sponge to main-

tain a constant jet within limits under different flagellar pressures brought about by varying environmental conditions. Thus partial closure of the oscules at moderately high temperatures increases the velocity of outflow to compensate for the fall in pressure associated with decreased flagellar activity and assures that water laden with waste products is carried out of range of the incurrent pores.

**Feeding and Digestion.**—Feeding and digestive activities are best known in freshwater sponges. A set of sieves of decreasing mesh size filters the water as it passes through the dermal membrane and the incurrent canals into the flagellated chambers. The dermal pores measure  $50\ \mu$  in diameter, the prosopyles measure  $5\ \mu$  in diameter, and the spaces between the cytoplasmic tentacles of the collars vary from  $0.10$  to  $0.15\ \mu$ . Only the smallest particles can enter the flagellated chambers where, coming in contact with the cell body of the choanocytes and ingested. Larger particles that pass through the dermal pores are ingested by the archaeocytes and collencytes, which form a reticulum in the incurrent canals or by the bases of the choanocytes. Particles, such as diatoms, too large to pass through the dermal pores may be ingested by the pinacocytes. Scattered observations recorded in the literature suggest that unicellular algae, flagellates, bacteria, and perhaps suspended organic detritus make up the food of sponges in nature. The finding of torulene, a red carotenoid occurring in the yeast *Torula rubra*, in several marine sponges suggests that some species feed commonly on red yeasts. Since digestion is intracellular, the size of the sponge cells involved places a limit on the size of the organisms ingested. In general, protozoans and rotifers are too large to be captured. It has been suggested that sponges feed solely by taking in dissolved organic substances; that this contention may be true in part has been neither confirmed nor disproved.

The archaeocytes appear to be the chief site of the digestive processes. Pinacocytes and collencytes also contribute to this function. In experiments powdered albumen is taken up by cells in the incurrent canals and by the choanocytes; this process is followed by ever increasing concentrations of the food in the archaeocytes, all of which are filled with vacuoles six hours later. Choanocytes, on the other hand, gradually lose the food particles that they have ingested and in ten hours are almost completely free of food. Transfer of particles from choanocytes to archaeocytes has been observed, but it is uncertain whether or not cell fusion occurs during this process. In the cells of a marine siliceous sponge, *Halichondria panicea*, the choanocytes have a higher concentration of proteolytic, lipolytic, and carbohydrate-decomposing enzymes than the archaeocytes. It appears likely, therefore, that in this species digestion is accomplished chiefly by the choanocytes. In calcareous sponges carmine particles and starch grains will concentrate chiefly in the choanocytes and will seldom appear in other cell types, although particles are apparently transferred by the choanocytes to egg cells.

In freshwater sponges, indigestible material is voided from blisterlike vacuoles in the archaeocytes, pinacocytes, and collencytes. The archaeocytes tend to migrate to the excurrent canals or the dermal membrane during later stages of digestion and there discharge indigestible particles.

**Reactions of Sponges.**—The slow rate of transmission of stimuli generally observed in sponges strongly suggests that transmission in these animals resides in the muscle cells, or myocytes. In studies on the freshwater sponge *Ephydatia fluviatilis*, the oscules remained open in both quiet and swiftly running water, but the oscular tube shortened in the latter case. Gentle mechanical stimuli and cutting into the flesh of the sponge had no effect on the oscules, but rubbing a needle around the edge of the mouth of the oscule caused the opening to contract immediately, and a wave of contraction traveled down the oscular tube at a rate of  $0.25\ \text{mm. per sec.}$

The activity of *Ephydatia fluviatilis* was not affected by light, but this sponge was more sensitive to temperature extremes than was a marine species, *Hymeniacidon heliophila*. The freshwater sponge showed no activity, and oscules were contracted at  $7^\circ\text{C}$  or below; exposure to temperatures of  $40^\circ\text{C}$  was lethal. Electric

cal stimulation of the oscular tip caused the opening to close, followed by a wave of contraction down the entire length of the tube at a rate of  $0.38\ \text{mm. per sec.}$

Evidence of the transmission of stimuli from one part of the sponge body to another was scant; electrical stimulation of the surface of the sponge at distances of 2 to 4 mm. from an oscule, however, caused an increase in the rate of flow of water from the oscules. It is possible that the choanocyte flagella had been stimulated to greater activity, suggesting that the stimulus had been transmitted from the surface to the flagellated chambers. Nerve-like cells run from the pinacocytes of some sponges to the choanocytes. The observations recorded above may be interpreted as providing indirect physiological evidence of conduction along such a pathway, although it is extraordinarily slow.

**Skeleton.**—All but a few species of sponges possess a skeleton made up of spicules or organic fibres or both. The skeleton is embedded in mesogloea, probably an important auxiliary supporting element in all sponges except the Hexactinellida, which lack it.

(ABOVE) JAMES R. LARSEN; (RIGHT) RALPH BUCHSBAUM

FIG. 5.—(ABOVE) SMALL PIECE OF A HORNY SPONGE SKELETON; (RIGHT) PHOTOMICROGRAPH OF SPONGIN FIBRES

Among calcareous sponges, the spicules are composed of calcium carbonate with an admixture of 4 to 14% magnesium carbonate; they are laid down as crystalline calcite. The spicules of Demospongiae and Hexactinellida are composed of hydrated silicon dioxide laid down in an amorphous form resembling opal. Organic fibres are the sole intrinsic skeletal elements in the bath sponges and their relatives. These fibres, which occur along with siliceous spicules in other Demospongiae, are composed of spongin, a collagenlike protein containing iodinated and brominated tyrosine among its component amino acids.

Sponge spicules vary greatly in form and are important in the identification of species. An elaborate nomenclature has been set up for the various types. An initial breakdown is made on the basis of size. Megascleres, the larger spicule types (usually  $100\ \mu$  to several millimetres in length), are the chief supporting elements in the sponge; in the Demospongiae they are often joined together by spongin fibres. Microscleres (usually  $5$  to  $50\ \mu$  in length), when present, are scattered in the mesogloea, where they presumably provide added support. A further subdivision of spicule types is based on the number of axes or rays present; in naming them an appropriate numerical prefix is added to the endings, *-axon*, when referring to the number of axes, or *-actine*, when referring to the number of rays or points.

Spicules are laid down as intracellular secretions of scleroblasts. In the Demospongiae each monaxonid (one axis) spicule is laid down in an individual cell by continuous deposition of hydrated silicon dioxide (opal) around an organic axial fibre. Tetraxonid spicules are also formed in single scleroblasts as far as is known. Microscleres are formed individually in special scleroblasts.

In the Calcarea, monaxonid spicules are secreted by binucleate scleroblasts. The mineral constituents of the spicule are deposited in crystalline form around an organic axial fibre. Each ray of triradiate and quadriradiate spicules is formed in a separate cell, the three or four rays eventually fusing basally to form the characteristic pattern.

FIG. 6.—SKELETAL SPICULES: (ABOVE) MEGASCLERE TYPES: (A) DIACTINAL MONAXONID (OXEA); (B) MONACTINAL MONAXONID; (C) TETRAXONID; (D) EQUIRADIATE TETRAXONID; (E) TRIACTINE; (F) HEXACTINE; (G) SILICEOUS LATTICEWORK OF A HEXACTINELLID; (H) DESMA; (I) SPONGIN FIBRES OF BATH SPONGE; (BELOW) MICROSCLERE TYPES: (A) SIGMA; (B) SPIRASTER; (C) CHELA; (D) ASTERS; (E-G) ASTERS; (H) HEXASTER; (I) AMPHIDISC

Hexactinellid spicules are laid down in syncytial scleroblast masses. The spicules are formed of hydrated silicon dioxide deposited around a central organic fibre in concentric layers separated by thin films of organic matter.

Spongin fibres are secreted by mesenchymal cells called spongioblasts. In *Haliclona elegans*, spongin rods are formed in cells that line up in rows. Successive rods then fuse to form a fibre that is freed following the degeneration of the spongioblasts. In *Haliclona simulans*, each cell forms a fibre several times its own length, and these fuse secondarily.

**Reproduction and Development.**—Sexual reproduction is of regular occurrence in all groups of sponges except the order Choristida of the class Demospongiae, where it is known in only a few species. Egg cells have been reported by various authors to originate from the flagellated cells of the larva, from choanocytes, or from archaeocytes. It is probable that eggs always develop from choanocytes that leave the flagellated chambers, lose their collars and flagella, and become amoeboid. (The lack of agreement on this point may result from various authors reporting different stages of the process.) Sperm cells apparently arise from choanocytes. In freshwater sponges, certain choanocytes lose their flagella, become amoeboid, leave the flagellated chambers, and transform into spermatogonia. In the bath sponge *Hippospongia communis*, all the choanocytes in a chamber transform simultaneously into spermatogonia and then develop into sperm.

In the Calcarea and several species of Demospongiae, fertilization is accomplished by way of a carrier cell that transfers the sperm to the egg. This process is probably of general occurrence in these two classes of sponges but is not yet known in the Hexactinellida. In both Calcarea and Demospongiae, sperm cells enter choanocytes; the latter then lose their collars and flagella and migrate to a position adjacent to the egg. The sperm, which has lost its tail and has enlarged, then enters the egg cell (presumably following fusion of the carrier cell and egg). Subsequent development of the embryo follows one of several courses characteristic of the different groups.

In the development of calcareous sponges of the subclass Cal-

caronea (including the genera *Leucosolenia*, *Sycon*, and *Grantia*), the fertilized egg cleaves in the meridional plane three times followed by an equatorial cleavage giving rise to a 16-celled embryo, which always lies just beneath the maternal choanocyte layer. At the 16-celled stage, the tier of eight cells lying in contact with the maternal tissue is destined to give rise to pinacocytes, collencytes, and scleroblasts in the adult sponge; the other eight cells are future choanocytes and amoebocytes. The latter eight cells continue to divide and develop flagella, and the embryo develops into a hollow blastula, called a stomoblastula. The stomoblastula has an opening in the group of eight cells that lie adjacent to the maternal choanocyte layer and that have undergone no further division up to this time. The embryo now turns inside out, the flagellated cells pushing out through the opening mentioned. The flagella are now external and in a position to propel the larva when it becomes free swimming. The hollow larva, now called an amphiblastula, consists of a layer of flagellated cells at one pole and nonflagellated cells at the opposite pole. Some of the flagellated cells have passed into the interior, lost their flagella, and will give rise to amoebocytes. Near the junction of the flagellated and nonflagellated cells lies a circle of four "cross cells" that are apparently light sensitive and help to orient the larva.

Following a short free-swimming life, the amphiblastula settles on a suitable substrate by its anterior end, and gastrulation occurs by invagination of the flagellated hemisphere or by downgrowth of the nonflagellated cells. The larva metamorphoses into a small tubular asconoid sponge (olynthus) and may retain this grade of construction or differentiate to a syconoid or leuconoid structure according to the species.

Among calcareous sponges of the subclass Calcinea (such as *Clathrina*), cleavage results in a hollow blastula consisting of a single layer of flagellated cells. The posterior pole is marked in some species by the presence of one to several nonflagellated cells. During the free-swimming period of the larva, some of the flagellated cells lose their flagella and wander into the interior of the embryo from all points except the anterior pole, or at the posterior pole only. The resulting solid larva, with internal ectomesenchyme, is known as a parenchymella and soon fixes to the substrate by its anterior end and flattens out. Metamorphosis involves a change in the relative positions and functions of the larval cells. The peripheral flagellated cells migrate through the central mass of nonflagellated cells and form the lining of the spongocoel as choanocytes. An olynthus is thus formed that will develop into the adult sponge.

Among the Demospongiae, most species develop by way of parenchymella larvae, but a few forms, presumed primitive, have amphiblastula larvae. In the skeletonless genus *Oscarella*, for example, representing the basal stock of the subclass Tetractinomorpha, cleavage results in a solid embryo, or morula, that later hollows out by disintegration (cytolysis) of the interior cells, rich in food reserves. The free-swimming larva is an amphiblastula composed of a single layer of flagellated cells. Near the posterior pole is a circle of cells bearing refractive rods; these cells are presumably light sensitive and help to orient the larva. The larva soon settles on its anterior end and flattens out. Gastrulation occurs as the anterior half of the larva invaginates. After the blastopore closes, the internal layer of cells is thrown into folds that are pinched off to form cavities, the future flagellated chambers. A depression in the ectoderm forms at the posterior pole and deepens, giving off branches that push their way among the flagellated chambers and finally open into them. This constitutes the excurrent canal system. The incurrent system forms as a series of surface depressions that enlarge and unite with the flagellated chambers. This type of development and metamorphosis occurs only in the family Plakinidae among Demospongiae.

*Halisarca*, a skeletonless genus of sponges belonging to the subclass Ceractinomorpha of the class Demospongiae, has parenchymella larvae, as do most members of this class. As in the Calcarea, these larvae have an outer layer of flagellated cells and an inner mass of cells that will give rise to the dermal membrane and mesenchyme cells. After the larva has settled, the flagellated cells lose their flagella, migrate into the interior, and differentiate

into choanocytes. A single internal cavity develops within the young sponge, now called a rhagon, and an oscular opening breaks through at the apex. In most Demospongiae the newly settled sponge or rhagon has a simple leuconoid canal system in which the flagellated chambers become isolated between the in-current and excurrent canals.

*Parrea*, a hexactinellid sponge, has cleavage that results in a solid blastula. At a later stage an outer layer of closely packed cells surrounds a transparent jellylike material in which amoeboid cells wander. Tetractinal spicules and choanocytes (at first without collars and flagella) develop before the larva is set free from the parent sponge. Upon settling, the larva metamorphoses into a small tubular sponge with a terminal osculum, and pentactinal and hexactinal spicules soon develop.

**Asexual Reproduction.**—The formation of asexual reproductive bodies, called gemmules, is characteristic of almost all freshwater sponges and of many marine species. Gemmules are made up of masses of archaeocytes laden with food reserves in the form of lipids and proteins. In freshwater sponges, the inner mass of archaeocytes is surrounded by a layer of columnar cells that secrete a double layer of spongin around the archaeocytes, as well as by a protective layer of spicules that vary in shape according to the species and are useful in classification. The gemmules of marine sponges are also made up of food-laden archaeocytes, which are, in some cases, enclosed in a spongin coat that may be provided with spicules.

Freshwater sponge gemmules and those of a few marine species carry the species over periods of unfavourable conditions, such as drought or high or low temperatures, during which times the adult sponges degenerate. Germination of the gemmules follows the return of favourable conditions. In many marine sponges gemmules may be found at all seasons, and the adults show no seasonal degeneration. Intertidal marine sponges in temperate regions often remain alive during the winter season, but in some species the internal cellular structure transforms into a uniform mass of amoebocytes. The normal adult structure redifferentiates upon return of favourable conditions.

Asexually produced gemmules that develop into free-swimming flagellated larvae similar in structure to sexually produced larvae have been reported in several species of marine Demospongiae and Hexactinellida.

Budding, another type of asexual reproduction found commonly in sponges, is of especially frequent occurrence among tetractinomorphic Demospongiae. In *Tethya*, for example, buds form from groups of archaeocytes that migrate to the tips of projecting spicule bundles. The buds eventually fall off and develop into new individuals.

**Regeneration.**—Sponges have remarkable powers of regeneration; any piece cut or broken from an adult sponge is very likely to attach to a suitable substrate and reform a functional individual. Suspensions of sponge cells prepared by squeezing fragments of adults through fine bolting silk will reorganize to form numerous small, functional individuals. According to most authors, the reconstitution of a new individual from dissociated cells results from the sorting out and migration of the various cell types to the positions that they characteristically occupy in the adult, but some observers report that choanocytes dedifferentiate, are phagocytized, or die, and later regenerate from other cell types.

After dissociation, masses of cells form as a result of the random movement of archaeocytes, amoebocytes, and other cells, including choanocytes that can put forth pseudopodia, as well as move by means of their flagella. There is some evidence to indicate that the adherence of cells as they come into contact with one another

is a result of antigen-antibodylike forces.

If the cells of two species of sponges of different colours are mixed in suspension, they eventually sort out to form aggregates composed of cells of one species or the other.

**Biochemistry.**—Ten different sterols have been isolated from sponges, including several so far unknown in any other organisms. Twenty or more different fatty acid components of sterols occur in each of two marine sponges, including a predominance of acids with 26 or 28 carbon atoms (unsaturated fatty acids with more than 24 carbon atoms are of rare occurrence among animals). Also of interest is the fact that sterols, which are most diverse in sponges, have been reduced in number during the course of animal evolution: in man only cholesterol and a few sex hormones are synthesized.

Sponges contain deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), characteristic of all animal groups. A methyl ether, anethole, and related substances (previously known only as components of plant oils) were isolated from a marine sponge and may be responsible for the odour of certain sponges. The spongin fibres characteristic of most Demospongiae have a structure similar to that of vertebrate collagens.

Chemical analyses of sponge pigments reveal that a majority of them are carotenoids, the most widely distributed animal biochromes. Carotenes have been found more commonly than xanthophylls, however, contrary to the situation in most marine plants and animals. Also present are chromolipoids, a porphyrin, and melanins.

**Organisms Associated with Sponges.**—Predators of sponges include chitons, snails, nudibranch slugs, and fish. Larvae of the neuropteran insect family Sisyridae (spongilla flies) live in, and feed upon, freshwater sponges. Many types of animals take up their abode in the natural cavities of marine sponges or form burrows of their own, but the exact nature of these relationships is little known. Hydroids, sea anemones, zoanthids, nematodes, polychaetes, octopuses, copepods, barnacles, isopods, amphipods, shrimps, brittle stars, and fishes are among the animals that dwell in temporary or permanent association with sponges. Pairs of shrimps (*Spongicola*) often inhabit the spongocoel of Venus's-flower-basket (*Euplectella*), a deep-sea hexactinellid. The shrimps are presumably imprisoned for life in the rigid siliceous reticular skeleton. *Suberites domunculus* (class Demospongiae) habitually lives on snail shells occupied by hermit crabs. Decorator crabs often choose pieces of sponge to plant or hold on their backs, presumably as a form of camouflage. Hydroids, bryozoans, acidians, and other encrusting competitors of sponges for substrate may overgrow sponge colonies or be overgrown by them.

Many freshwater and shallow-water marine sponges harbour unicellular green algae in their amoebocytes. The sponges probably obtain some nutriment from the algae in the form of sugars, since the algal cells fail to synthesize starch when growing in

sponges, and dying algal cells may be consumed as well. Apparently both the algae and the sponges can survive independently. Young sponges are reinfected with algae from free-swimming algal zoospores in the water. Unicellular and filamentous blue-green and green algae, as well as coralline algae, often grow in sponge colonies, and it is reported that bacteria living in the cells of some species of sponges impart colour to the animals. The significance of these relationships is unknown.

**Boring Sponges.**—Sponges of the family Clionidae (class Demospongiae) live in galleries that they excavate in mollusk shells, corals, limestone, and other calcareous materials. Consequently,

FIG. 7.—PARENCHYMELLA LARVA OF HALISARCA

FIG. 8.—GLASSLIKE SKELETON OF VENUS'S-FLOWER BASKET (EUPLECTELLA)

these sponges are economically significant as weakeners of limestone breakwaters and oyster shells, rendering the latter difficult to process in canning factories.

The boring activities of clionids are accomplished by the excavation of numerous small chips of calcium carbonate. Pseudopodia and cytoplasmic films put out by sponge cells in contact with a calcareous substrate apparently insinuate themselves into the calcium carbonate, possibly by the localized secretion of an acid, and thus remove particles of relatively uniform size. The cells can also bore through conchiolin, a proteinaceous substance that separates successive layers of calcareous matter in mollusk shells, but they accomplish this less readily than they excavate the calcareous layers.

Clionids have monactinal megascleres with terminal knobs and may also have microscleres in the form of spiny diactinal spicules or spirasters or both. The sponges are not parasitic but feed on phytoplankton and detritus carried in the water currents maintained through their bodies as in other sponges. Dermal pores and oscules are localized on contractile tubules that protrude through holes in the calcareous substrate.

### CLASSIFICATION AND RELATIONSHIPS

The subdivision of the phylum Porifera into three classes—Calcarea, Hexactinellida, and Demospongiae—is based on the chemical composition of the skeletal elements. The Calcarea includes species with one- to four-rayed spicules made of calcium carbonate. Members of the Hexactinellida have siliceous spicules that are basically six rayed. Finally, the Demospongiae includes species with siliceous spicules that are usually one to four rayed, and never six rayed. Collagenlike fibres are often present as component supporting structures along with siliceous spicules in the Demospongiae, and in some species, including the bath sponges of commerce, such fibres make up the sole intrinsic skeletal elements.

**Hexactinellida.**—This class comprises sponges with skeletons made up basically of hexactinal siliceous spicules and lacking in spongin. They are exclusively marine and occur in the deeper waters of all seas from depths of about 25 m. to 8,500 m. The skeletal framework is made up of three systems of spicules: dermal, lying just beneath the dermal membrane; gastral, lying beneath the membrane bounding the spongocoel; and parenchymal, lying between the other two systems. The parenchymal megascleres of many species become fused to their neighbours to form a rigid latticework. The soft parts stretch across cavities between the skeletal systems and have the form of cobweblike or filmy trabeculae. Five regions may be distinguished in the body wall passing from the outside layer to the spongocoel: the dermal membrane, perforated by pores; the subdermal trabecular network in the midst of which subdermal cavities and incurrent canals may be identified; the thimble-shaped flagellated chambers (made up of choanocytes with fused cell bases), arranged side by side in a single layer, usually inside the parenchymal megascleres; the subspongocoelic trabecular network into which the flagellated chambers open and in which excurrent canals may be present; the perforated membrane lining the spongocoel or central cavity. From the spongocoel, water passes out of the terminal oscule, which in some species is covered by a sieve plate reinforced by a spicular network.

In the subclass Hexasterophora the parenchymal microscleres are typically hexasters (small, six-rayed spicules that often have branched ends). The sponges are commonly fixed firmly by the base to a hard substrate, but some species anchor themselves in soft bottom sediments by means of a basal spicule tuft or mat. The parenchymal megascleres are often fused into a rigid framework. Examples: *Hexactinella*, *Aphrocallistes*, *Farrea*, *Dactylocalyx*, *Euplectella*, *Rhabdocalyptus*.

Members of the subclass Amphidiscophora have parenchymal microscleres called amphidiscs (the distal ends of the rays bear an umbrellalike expansion). The parenchymal megascleres are always free and never fuse to form a rigid network. The sponges anchor themselves in the bottom sediments by basal tufts of spicules. Examples: *Pheronema*, *Hyalonema*.

**Calcarea.**—This class is characterized by sponges with a skele-

ton made up of spicules of calcium carbonate. The species may be vase-shaped compact structures, a loose network of thin tubes, or irregular massive colonies. The Calcarea are mostly small in size and inhabit the shallow waters of all seas, from intertidal regions to depths of 200 m.; a few species extend down to depths of at least 800 m.

In the subclass Calcaronea amphiblastula larvae are produced. The nuclei of the choanocytes are apical in position, with the flagellum in each case arising directly from the nucleus. The spicules are triradiate and characteristically have one ray longer than the other two. The canal system is asconoid, syconoid, or leuconoid. Examples: *Leucosolenia*, *Sycon*, *Grantia*, *Lelapia* (with a rigid skeleton composed of tracts or bundles of modified three-rayed spicules).

The subclass Calcinea contains species that produce parenchymella larvae. The nuclei of choanocytes are basal in position, with the flagellum in each case arising independent of the nucleus. At least some of the triradiate spicules in most species have equal rays and equal angles between the rays. The canal system is asconoid, radiate, or leuconoid. Tentatively included among the Calcinea are the pharetronid Calcarea, which have a rigid skeleton composed of fused spicules or of a calcareous network. Examples: *Clathrina*, *Leucetta*, *Petrobiona* (a pharetronid).

**Demospongiae.**—This class comprises sponges with a skeleton of one- to four-rayed siliceous spicules or of spongin fibres or both. A skeleton is lacking in several genera regarded as primitive. The Demospongiae are the most abundant and widely distributed sponges, occurring from intertidal regions down to depths of at least 5,500 m. in the sea. The Spongillidae is the only freshwater family. The species vary greatly in form and size, ranging from thin encrustations several centimetres in diameter to huge cake-shaped species measuring up to 2 m. in diameter.

Included among the Demospongiae are many species with desmas as spicules. These develop as a result of secondary deposits of silica around ordinary monaxonid or tetraxonid spicules. Often adjacent desmas articulate or interlock to form a stony skeleton. Such sponges are often called "lithistids," but they seem to have evolved independently among the several orders of Demospongiae and do not constitute a natural group of their own.

In the subclass Tetractinomorpha the skeleton is variously composed of scattered equirayed tetraxonid spicules and their derivatives, or of tetraxonid (usually triaenes) and monaxonid spicules arranged in a radiate pattern, or of monaxonid spicules alone arranged in radiating or plumose tracts. Spongin is scarce except among the axinellids. Microscleres are chiefly asters, streptasters, sigmas, and small monactinal or diactinal forms often provided with spines. Most of the species of this subclass, for which reproductive processes are known, are oviparous. The larvae of the primitive family Plakinidae are amphiblastulae, but parenchymellae occur in most species where sexual reproduction is known.

BY COURTESY OF THE AMERICAN MUSEUM OF NATURAL HISTORY

FIG. 9.—FRESHWATER SPONGE (SPONGILLA), ENCRUSTED ON TWIGS

to occur. Tetractinomorph sponges vary greatly in shape, from encrustations and spherical forms to massive and branching colonies. They occur in all seas from tidal waters down to depths of at least 5,500 m. Examples: *Oscarella* (lacking a skeleton), *Plakina*, *Geodia*, *Cinachyra*, *Tethya*, *Suberites*, *Cliona*, *Azinella*.

Members of the subclass Ceractinomorpha are Demospongiae with a skeleton of monaxonid spicules joined together by more or less spongin or of spongin fibres alone. Microscleres of many varieties may occur, but asters are never present. Members of this subclass are viviparous and have parenchymella larvae. Examples: *Halisarca* (lacking a skeleton), *Aplysilla*, *Spongia*, *Haliciona*, *Spongilla* (freshwater), *Microciona*, *Halichondria*.

**Origin and Relationships.**—The origin of sponges and their relationship to other multicellular animal groups are still unsettled questions. As to their origin it seems most likely that they have descended from a group of flagellates. The structure of the choanocytes of sponges is almost identical to that of the component cells of choanoflagellate colonies, and it is these zooflagellates that are generally cited as the most probable sponge ancestors. The collar of both types of cells is now known to be composed of cytoplasmic filaments as a result of the electron microscope studies of Kilian and Rasmont. Choanoflagellates are holozoic and capture food by means of the collar. Among existing protists, the choanoflagellates thus appear to be nearest to the ancestral line of sponges.

Fossil sponges are known from Cambrian and succeeding strata. Scattered records of sponge spicules in Precambrian rocks are in need of confirmation. The best-preserved fossil sponges belong to those groups that have skeletons of articulated or fused spicules, namely, many families of hexacterophoran Hexactinellida, lithistid families among the Demospongiae, and the pharetronid Calcareia. Only isolated spicules of other sponge groups tend to be preserved except under unusually favourable conditions.

Undoubted fossil hexactinellids are first recorded in the Lower Cambrian. The group is exceptionally well represented in Devonian strata, in the Lower Carboniferous, in the Lower Jurassic, and in the Cretaceous. Species of the class Demospongiae are also found in Cambrian strata and upward; they reach a peak of abundance as lithistids in Cretaceous beds. Calcareous sponges have been reported from Cambrian strata, but the first certain fossil remains occur in the Devonian Period. Pharetronids are well represented from Permian and successive strata.

The question now arises as to what relationship sponges bear to other multicellular animals. According to some authors, the sponges represent a distinct subkingdom of animals that has arisen independently of all other metazoan groups. The uniqueness of the sponge body plan and peculiarities of fertilization and development are cited in support of this hypothesis. Special importance is given to the fact that in both amphiblastula and parenchymella larvae the flagellated cells that give rise to the choanocytes occupy the anterior hemisphere, while the nonflagellated ectomesenchymal cells are posterior in position. Such an arrangement is opposite that occurring in all other multicellular animals, in which the presumptive endoderm occupies a posterior position in the embryo and the ectoderm is anterior. Whether the germ layers of sponges are reversed in comparison with other animals or whether the choanocytes of sponges cannot be homologized with the endoderm of other Metazoa, this fact supports the wide separation of sponges from all other multicellular forms. The subkingdom Parazoa or Enantiozoa has been set up for the sponges by proponents of this theory.

Other authors have argued in favour of the basic similarity of the development of sponges and other Metazoa. The supposed

inversion of the germ layers in sponge embryos is explained as a consequence of the inversion of the surfaces of the amphiblastula as described above for the Calcareia. Sponges have been regarded as an offshoot from the evolutionary line that gave rise to the coelenterates. It is of interest to point out that collar processes have been observed to surround the flagella of coral epithelial cells. In *Mussa angulosa* the processes give rise to between 9 and 12 microvilli, giving the cell a structure strikingly similar to a sponge choanocyte with its collar of cytoplasmic filaments. Minute microvilli are apparently also characteristic of the ciliated epithelia of mollusks and vertebrates.

(W. D. H.)

## ARTIFICIAL SPONGES

Artificial sponges are produced by the chemical expansion of natural crude rubber, such synthetic rubbers as neoprene, and certain plastics, of which polyvinyl chloride is a type.

In processing, the treatment of neoprene may be taken as typical of the sponge rubbers. Basically, neoprene sponge is compounded of sulfur-modified neoprene, magnesia, zinc oxide, an antioxidant, a mineral filler, such as channel carbon black or whiting, and an expanding or "blowing agent," which may be sodium bicarbonate. The stock may be treated further with other chemical agents as special needs indicate. A lubricant is used to keep the cells from sticking together. The stock is softened on mill rolls and then mixed. The chemicals are added when the neoprene becomes elastic and before it reaches its granular phase. Mixing continues until the stock is plastic. The rate of the subsequent curing process is carefully controlled to ensure a desired degree of "blow."

Sponge rubber can be processed in sheets on a machine called a calender. They can be produced also in slabs, die-cut shapes, and molded forms. They have many uses, of which gasketing, insulation, cushioning, shock absorption, and vibration damping are examples. Similar to sponge rubbers are expanded rubbers and expanded plastics having a closed-cell structure, which possess a superior insulating quality and greater buoyancy. Closed-cell polyvinyl chloride is widely used for floats, whereas the open-cell form is useful as cushioning.

Foam rubber, used in bedding, upholstery, and cushioning, is made from rubber latex chemically foamed to produce a soft structure of interconnecting cells.

See also references under "Sponges" in the Index. (E. L. Y.)

**BIBLIOGRAPHY.**—An excellent general account of the sponges is given by L. H. Hyman in *The Invertebrates*, vol. i, *Protozoa Through Ctenophora*, pp. 284–364 (1940); more recent literature is reviewed by L. H. Hyman in *The Invertebrates*, vol. v, *Smaller Coelomate Groups*, pp. 715–718 (1959); E. J. Cresswell, *Sponges* (1930), an account of commercial sponges; novel phylogenetic speculations may be found in E. N. Willmer, *Cytology and Evolution* (1960).

(W. D. H.)

**SPONTANEOUS GENERATION**, in biology, is the theory, now disproved, that living organisms at present arise from nonliving matter. It is sometimes referred to as abiogenesis, as opposed to biogenesis, the now-established fact that living organisms arise only from the reproduction of previously existing organisms.

See **BIOLOGY: History: Biogenesis Versus Abiogenesis**; **LIFE, ORIGIN OF**.

**SPONTINI, GASPARO LUIGI PACIFICO** (1774–1851), Italian opera composer, whose early Paris operas, based on heroic historical themes, are representative of the spirit of the Napoleonic era, and whose German operas had some influence on the early works of Wagner. He was born at Majolati, Ancona, on Nov. 14, 1774, of humble parents. In 1793 he studied singing and composition at Naples, and his first opera, *I Puntigli delle donne*, was produced in Rome in 1796, followed by others given at Venice, Florence, Naples, and Palermo. In 1803 he went to Paris, where, after writing unsuccessful works in the light French style, he collaborated with the writer Étienne de Jouy in dramatic operas, producing *Milton* (1804) and his masterpiece, *La Vestale* (1807). The success of the latter, which had been given at the Opéra under the patronage of the empress Josephine, led to the award of a prize to Spontini from Napoleon. *Fernand Cortez* (1809), the subject of which appealed to Napoleon in view of his plans for a Spanish war, was similarly successful, and the following year Spontini was

FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA"; MCGRAW-HILL, 1940

FIG. 10.—PROTEROSPONGIA, A COLONIAL CHOANOFAGELLATE CONSIDERED AS A PROBABLE LINK BETWEEN THE PROTOZOANS AND SPONGES

appointed director of the Italian Opera in Paris.

As a conductor Spontini introduced to Paris works of Haydn and Mozart. In 1814 he was appointed court composer by Louis XVIII and wrote various stage works in glorification of the Restoration, among them *Pélage, ou le roi de la paix* (1814). Later he held a similar appointment at the court of Frederick William III in Berlin, where, between 1821 and 1829, he produced *Olympia* (earlier given in Paris as *Olympie*; the libretto, which was based on Voltaire, was translated into German by E. T. W. Hoffmann); *Nurmahal* (based on Thomas Moore's *Lalla Rookh*); *Alcidor*; and *Agnes von Hohenstaufen*.

Spontini spent his later years in France and Germany and eventually returned to his birthplace, Majolati, where he died on Jan. 24, 1851.

**BIBLIOGRAPHY.**—G. Abraham, "The Best of Spontini" in *Music and Letters* (April, 1942); A. Ghislanzoni, *G. Spontini* (1951); A. Belardinelli, *Documenti spontiniani inediti*, 2 vol. (1955).

**SPOON**, an implement consisting of a bowl-shaped receptacle supported by a stem or handle. The word originally meant a piece of some such substance as wood or horn carved from a larger section. (The Greeks and Romans adopted more permanent materials, such as bronze and sometimes silver.) Although it is the tablespoon that has largely engaged the interest of collectors and writers, it was not the only kind in antiquity; some of the most interesting and beautiful ancient spoons had ceremonial or toilet use, such as the long incense spoons depicted in Egyptian art and the cosmetic spoons, often engagingly carved with anthropomorphic or zoomorphic handles, that have survived from Egyptian burials.

The history of tablespoons belongs to that of western culture. Spoons made of silver were among the first pieces of plate that a successful medieval citizen strove to acquire; they were sufficiently esteemed to be bequeathed singly. Long, pointed bowls characterize the few early medieval spoons excavated in the British Isles. The English coronation spoon used for the anointing of the sovereign belongs to this type and period (see **CROWN** and **REGALIA**). The shape of bowl and stem evolved according to table manners in the course of the centuries. The fig-shaped bowl prevailed from the later Middle Ages, the stem culminating either in a conventional pattern of knop or in one especially ordered by the customer.

In general favour were "Maidenhead" knops, representing a female bust, traditionally that of the Virgin, and "Apostle" knops. Entire sets of these apostle spoons, 12 in number (or 13 when Jesus Christ was included), rarely survive, because it was common to present single spoons as christening gifts.

Matching sets of spoons and forks were common by the mid-18th century in various standard

patterns; the modern form of tablespoon, with the stem ending in a rounded curve turned downward, was adopted about 1760. For the manufacture of spoons, see **FLATWARE**.

See G. E. P. and J. P. How, *English and Scottish Silver Spoons*, 3 vol. (1952-57); C. C. Oman, *English Domestic Silver*, 4th ed. (1959).

(J. F. H.)

**SPOONBILL**, any one of six species of moderately large wading birds constituting the subfamily Plataleinae and, with the ibises (*q.v.*), the family Threskiornithidae (order Ciconiiformes). The head is partly or entirely bare, the plumage white (except in the roseate spoonbill), often with a rosy tinge, some

with a nuptial crest or foreneck plumes. They differ from ibises in having a long nearly straight bill, narrow in the middle and broad and flat at the end, which they immerse in feeding, swinging it from side to side and sifting small animals from the mud and water of estuaries, salt-water bayous and lakes. In flight they flap steadily, usually without sailing. They breed in colonies, often with ibises and herons, build a good nest of sticks; sometimes lined with leaves or bark, among reeds or in a low bush or tree about ten feet up, and lay three to five white eggs blotched with reddish-brown.

The beautiful roseate spoonbill (*Ajaia ajaja*), 32 in. long, head and throat bare, legs red, is deep pink with neck and upper back white, wing coverts and tail coverts deep carmine and tail and sides of breast tawny-buff. It ranges from the Gulf coast of Texas (and a very few in Florida), the West Indies and central Mexico to Argentina and Chile. In many places it was exterminated by plume hunters. The yellow-legged spoonbill (*Platibis flavipes*) of Australia is white with straw-coloured foreneck and a yellow forehead, upper throat and bill. The crested white spoonbill (*Platalea leucorodia*), 24 in., with cinnamon-buff on the foreneck, breeds in marshes of central and southern Europe and Asia, south to Egypt, India and Formosa; the black-billed spoonbill (*P. regia*), white with black wing tips and black legs, from Australia and New Zealand to New Guinea, Celebes, Moluccas and Solomons; the lesser spoonbill (*P. minor*), from Korea and southern Japan to southern China and the Philippines; the African spoonbill (*P. alba*), over Africa south of the Sahara and in Madagascar.

(G. F. Ss.)

**SPORADES** (modern Greek SPORÁDHEs), the "scattered islands" of the Aegean Sea, as distinct from the Cyclades (*q.v.*) grouped around Delos, and, usually, not including any of the coastal islands of Greece or Asia Minor. Both ancient and modern writers differ as to the list. Some or all of the islands in the south of the Cyclades—Melos (Mílos), Pholegandros (Folégandros), Sikinos, Thera (Thíra), and Anaphe (Anáfi)—were sometimes reckoned as Sporades. In modern times the name is applied to two groups.

The Northern Sporades lie northeast of Euboea (Évvoia): Skiathos, Skópelos (ancient Peparethos), Iliodhrómia (ancient Ikos), and the smaller islands to their east are included in the Greek *nomos* (department) of Magnisia, and, farther southeast, Skyros (*q.v.*) and adjacent islands are in that of Euboea. Both Skyros and the beautifully wooded Skiathos have excellent harbours. There has been little archaeological exploration conducted on the islands, but there are classical remains on Skyros and a notable find of Mycenaean goldwork from Skópelos (1936). Almost every householder in the islands is the owner, joint owner, or skipper of a sailing ship.

The Southern Sporades, lying off the southwest of Asia Minor in a roughly northwest-southeast band, are from north to south, as follows: Ikária, Pátmos (*q.v.*), Léros, Calymnos (Kálimnos), Astypalaea (Astipálaia), Cos (*q.v.*), Nisyros (Nísiros), Telos (Tílos), Symé (Símí), Khálki, Rhodes (*q.v.*), and many smaller islands. All but the first named formed part of the Dodecanese (*q.v.*). The Dodecanese were occupied by the Italians from 1912 to 1947.

See A. Philippson, *Die Griechischen Landschaften*, vol. iv (1959).

(J. Bo.)

**SPOROZOA**, a subphylum of Protozoa incorporating several problematic groups of microscopic parasites, among them *Plasmodium*, the causative agent of malaria. Their reproductive processes and life cycles are complex; spores are formed in some but not all members. See **PROTOZOA**.

\*A.L.—American League; N.L.—National League.

†One tied game.

**BASKETBALL.** Basketball originated in the United States (see the article BASKETBALL) where it is a major collegiate, amateur, and professional sport. In Olympic years since 1936 world amateur championships have been decided at the games (for table of champions see the article OLYMPIC GAMES); inter-Olympic world amateur championships are held under the auspices of the International Amateur Basketball Federation.

## World Amateur Championships\*

1943	St. John's (Bklyn.)

**BILLIARDS.** World professional billiard competition, constituted in 1870, had largely died out by 1932 because of the repetitive use of the nursery cannon (*see* the article **BILLIARDS**); world three-cushion championships were discontinued after 1953; and snooker was so dominated by Joe Davis, 1927-46, that professional championships fell into abeyance. New world amateur championships were instituted in 1951; pocket billiard competition has continued from 1878.

**World Amateur Championship**

Year	Champion
1951	R. Marshall; Austr.
1952	A. L. Drifffield; U.K.
1954	T. Cleary; Austr.

**BOWLS (LAWN BOWLS).** Bowls (lawn bowls or bowling on the green) is an organized sport in the United Kingdom, Australia, New Zealand, South Africa, Canada, and the United States, and accredited teams from these countries have exchanged visits intermittently (see the article *BOWLS*). The Inaugural World Championships were staged at Sydney, Austr., in 1966.

INGEMAR JOHANSSON WINNING THE WORLD HEAVYWEIGHT BOXING CHAMPIONSHIP FROM FLOYD PATTERSON, 1959

**BOXING.** There is no world governing body in professional boxing, therefore the status of "world champions" has varied from those globally recognized down to those recognized in one continent or even in a minority of U.S. states. In the compilation below claimants with a disputed status have been italicized. Nationalities relate to the country of birth.

## World Heavyweight Champions

Year	Champion	Year	Champion
1892	James J. Corbett*; U.S.	1935	James J. Braddock; U.S.
1897	Bob Fitzsimmons; U.K.	1937	Joe Louis; U.S.

### Lightweight Champions

(135 lb. but 133 lb. in the early years)

1896 George (Kid) Lavigne; U.S.  
1899 Frank Erne; Switz.  
1902 Joe Gans; U.S.  
1908 Battling Nelson; Den.  
1910 Ad Wolgast; U.S.  
1912 Willie Ritchie; U.S.  
1914 Freddie Welsh; U.K.  
1917 Benny Leonard; U.S.  
1925 Jimmy Goodrich; U.S.  
1925 Rocky Kansas; U.S.  
1926 Sammy Mandell; U.S.  
1930 Al Singer; U.S.  
1930 Tony Canzoneri; U.S.  
1933 Barney Ross; U.S.  
1935 Tony Canzoneri; U.S.  
1936 Lou Ambers; U.S.  
1938 Henry Armstrong; U.S.  
1939 Lou Ambers; U.S.  
1940 Lew Jenkins; U.S.  
1941 Sammy Angott; U.S.  
1942 Beau Jack; U.S.  
1943 Bob Montgomery; U.S.  
1943 Beau Jack; U.S.  
1944 Bob Montgomery; U.S.  
1944 Juan Zurita; Mex.  
1945 Ike Williams; U.S.  
1947 Ike Williams; U.S.  
1951 Jimmy Carter; U.S.  
1952 Lauro Salas; Mex.  
1952 Jimmy Carter; U.S.  
1954 Paddy DeMarco; U.S.  
1954 Jimmy Carter; U.S.  
1955 Wallace Bud Smith; U.S.  
1956 Joe Brown; U.S.  
1962 Carlos Ortiz; P.R.  
1965 Ismael Laguna; Pan.  
1965 Carlos Ortiz; P.R.

### Featherweight Champions (126 lb. but 118 lb. and 122 lb. in the early years)

1892 George Dixon; Can.  
1896 Frank Erne (122 lb.); Switz.  
1897 George Dixon (122 lb.); Can.  
1897 Solly Smith (120 lb.); U.S.  
1900 Terry McGovern (118 lb.); U.S.  
1901 Young Corbet III (126 lb.); U.S.  
1904 Abe Attell (122 lb.); U.S.  
1904 Tommy Sullivan (122 lb.); U.S.  
1908 Abe Attell; U.S.  
1912 Johnny Kilbane; U.S.  
1923 Eugene Criqui; Fr.  
1923 Johnny Dundee; It.  
1925 Louis (Kid) Kaplan; U.S.S.R.  
1927 Benny Bass; U.S.S.R.  
1928 Tony Canzoneri; U.S.  
1928 Andre Routis; Fr.  
1929 Battling Battalino; U.S.  
1932 Tommy Paul; U.S.  
1932 Kid Chocolate; Cuba  
1933 Freddie Miller; U.S.  
1936 Petey Sarron; U.S.  
1937 Henry Armstrong; U.S.  
1938 Joey Archibald; U.S.  
1940 Harry Jeffra; U.S.  
1941 Joey Archibald; U.S.  
1941 Chalky Wright; Mex.  
1942 Willie Pep; U.S.  
1946 Willie Pep; U.S.  
1948 Sandy Saddler; U.S.  
1949 Willie Pep; U.S.  
1950 Sandy Saddler; U.S.  
1957 Hogan Bassey; Nig.  
1959 Davey Moore; U.S.  
1963 Sugar Ramos; Cuba  
1964 Vicente Saldivar; Mex.

### World Bantamweight Champions

(118 lb. but 105, 112, and 116 lb. in the early years)

1890 George Dixon; Can.  
1882 Billy Plimmer; U.K.  
1894 Jimmy Barry (112 lbs.); U.S.  
1895 Pedlar Palmer; U.K.  
1899 Terry McGovern; U.S.  
1901 Harry Forbes; U.S.  
1903 Frankie Neil; U.S.  
1904 Joe Bowker; U.K.  
1904 Digger Stanley; U.K.  
1905 Jimmy Walsh; U.S.  
1907 Title vacant  
1908 Johnny Coulon; Can.  
1914 Kid Williams; Den.  
1915 Johnny Ertle; Aus.

1917 Pete Herman; U.S.  
1920 Joe Lynch; U.S.  
1921 Pete Herman; U.S.  
1921 Johnny Buff; U.S.  
1922 Joe Lynch; U.S.  
1924 Abe Goldstein; U.S.  
1924 Eddie Martin; U.S.  
1925 Charlie Rosenberg; U.S.  
1927 Bud Taylor; U.S.  
1929 Al Brown; Pan.  
1932 Al Brown; Pan.  
1934 Sixto Escobar; P.R.  
1935 Baltasar Sangchili; Sp.  
1935 Lou Salica; U.S.  
1935 Sixto Escobar; P.R.  
1937 Harry Jeffra; U.S.  
1938 Sixto Escobar; P.R.  
1941 Lou Salica; U.S.  
1942 Manuel Ortiz; Mex.  
1947 Harold Dade; U.S.  
1947 Manuel Ortiz; Mex.  
1950 Vic Towel; S.Af.  
1952 Jimmy Carruthers; Austr.  
1954 Robert Cohen; Alg.  
1956 Mario d'Agata; It.  
1957 Alphonse Halimi; Alg.  
1959 Jose Becerra; Mex.  
1960 Alphonse Halimi; Alg.  
1960 Eder Jofre; Braz.  
1961 Eder Jofre; Braz.  
1965 Fighting Harada; Jap.

### World Flyweight Champions (112 lb.)

1913 Sid Smith; U.K.  
1913 Bill Ladbury; U.K.  
1914 Percy Jones; U.K.  
1914 Joe Symonds; U.K.  
1916 Jimmy Wilde; U.K.  
1923 Pancho Villa; Phil.  
1925 Fidel la Barba; U.S.  
1927 Izzy Schwartz; U.S.  
1930 Midget Wolgast; U.S.  
1930 Frankie Genaro; U.S.  
1931 Young Perez; Tun.  
1932 Jackie Brown; U.K.  
1935 Benny Lynch; U.K.  
1938 Peter Kane; U.K.  
1943 Jackie Paterson; U.K.  
1947 Rinty Monaghan; U.K.  
1950 Terry Allen; U.K.  
1950 Dado Marino; Hawaii  
1952 Yoshio Shirai; Jap.  
1954 Pascual Perez; Arg.  
1960 Pone Kingpetch; Thai.  
1962 Fighting Harada; Jap.  
1963 Pone Kingpetch; Thai.  
1963 Hiroyuki Ebihara; Jap.  
1964 Pone Kingpetch; Thai.  
1965 Salvatore Burrundi; It.  
1966 Walter McGowan; U.K.  
1966 Chartchai Chinoi; Thai.

The events were held in Vaxholm, Swed., 1938; Copenhagen, Den., 1950; Macon, Fr., 1954; Prague, Czech., 1958; Jajce, Yugos., 1963; East Berlin, Ger., 1966.

#### Kayak Singles (K. 1) 500 m.

1950 F. Kobberup; Den.  
1954 G. Fredriksson; Swed.  
1958 S. Kaplaniak; Pol.  
1963 A. Vernescu; Rum.  
1966 A. Vernescu; Rum.

#### Kayak Singles (K. 1) 1,000 m.

1938 Widmark; Swed.  
1950 G. Fredriksson; Swed.  
1954 G. Fredriksson; Swed.  
1958 F. Briel; W. Ger.  
1963 E. Hansen; Den.  
1966 A. Schaparenko; U.S.S.R.

#### Kayak Singles (K. 1) 10,000 m.

1938 Widmark; Swed.  
1950 T. Strömberg; Fin.  
1954 Hutlacskey; Hung.  
1958 T. Strömberg; Fin.  
1963 F. Briel; W. Ger.  
1966 M. Hes; Hung.

#### Kayak Pairs (K. 2) 500 m.

1950 Glasser, Hedberg; Swed.  
1954 Steinhauer, Miltenberger; W. Ger.  
1958 Kaplaniak, Zielinski; Pol.  
1963 Nicoara, Ivanov; Rum.  
1966 Vernescu, Sciutnic; Rum.

#### Kayak Pairs (K. 2) 1,000 m.

1938 Triebe, Eberle; Ger.  
1950 Glasser, Hedberg; Swed.  
1954 Meszaros, Meszaros; Hung.  
1958 van der Moere, Verbrughe; Belg.  
1963 Nicoara, Ivanov; Rum.  
1966 Schaparenko, Stezenko; U.S.S.R.

#### Kayak Pairs (K. 2) 10,000 m.

1938 Johansson, Berndtsson; Swed.

1950 Akerlund, Wetterström; Swed.

1954 Raub, Wiedermann; Aus.

1958 Uranyi, Fabian; Hung.

1963 Fabian, Timar; Hung.

1966 Szoelloesi, Fabian; Hung.

#### Kayak Fours (K. 4) 1,000 m.

1938 Kube, Bruggeman, Gebrüder, Strahtman; Ger.

1950 Pihi, Eriksson, Pettersson, Haeppling; Swed.

1954 Vagyosky, Kovacs, Nagy, Szigetti; Hung.

1958 Scheuer, Lietz, Schmidt, Kleine; W. Ger.

1963 Perleberg, Krause, Rossberg, Lange; E. Ger.

1966 Sciutnic, Turcas, Ivanov, Calenic; Rum.

#### Kayak Fours (K. 4) 10,000 m.

1950 Andersson, Gustavsson, Johansson, Andersson; Swed.

1954 Pihl, Frick, Heurlin, Andersson; Swed.

1958 Scheuer, Lietz, Schmidt, Kleine; W. Ger.

1963 Fabian, Timar, Koltai, Novotny; Hung.

1966 Shchushchikov, Grishchin, Morozov, Ionov; U.S.S.R.

#### Singles Relay 4 x 500 m.

1950 Sweden

1954 Sweden

1958 West Germany

1963 Rumania

1966 U.S.S.R.

#### Canadian Singles (C. 1) 1,000 m.

1938 Newmuller; Ger.

1950 Holecek; Czech.

1954 Parti; Hung.

1958 G. Bukharin; U.S.S.R.

1963 Ismailkious; Rum.

1966 D. Lewe; W. Ger.

#### Canadian Singles (C. 1) 10,000 m.

1950 Boutigny; Fr.

1954 Vokner; Czech.

1958 G. Bukharin; U.S.S.R.

1963 M. Zamotin; U.S.S.R.

1966 A. Hajba; Hung.

#### Canadian Pairs (C. 2) 1,000 m.

1938 Probst, Weinstabl; Ger.

1950 Bvzak, Kudrna; Czech.

1954 Liebhart, Lulla; Aus.

1958 Ismailkious, Alexe; Rum.

1963 Jakovici, Sidorov; Rum.

1966 Calabiciov, Covaliov; Rum.

#### Canadian Pairs (C. 2) 10,000 m.

1938 Karlik, Brzak; Czech.

1950 Bvzak, Kudrna; Czech.

1954 Wieland, Halmal; Hung.

1958 Oschenkov, Silaev; U.S.S.R.

1963 Geister, Makarenko; U.S.S.R.

1966 Maxim, Simonov; Rum.

#### Kayak Singles (K. 1) Women 500 m.

1938 Kalka; Fin.

1950 Saimo; Fin.

1954 Zenz; Ger.

1958 Kislova; U.S.S.R.

1963 Zhubina; U.S.S.R.

1966 Pinayeva; U.S.S.R.

#### Kayak Pairs (K. 2) Women 500 m.

1938 Paulisova, Zuolankova; Czech.

1950 Salmo, Gronholm; Fin.

1954 Punter, Banfalvi; Hung.

1958 Shubina, Gruzintseva; U.S.S.R.

1963 Zimmerman, Esser; E. Ger.

1966 Kobuss, Ulze; E. Ger.

## CHESS\*

## World Champions

1866	W. Steinitz; Aus.
1894	E. Lasker; Ger.

**Tour de France—Postwar Champions.** The Tour was inaugurated in 1903 over courses of varying length and severity—the longest being 3,567 mi. for the race of June 20–July 18, 1926. The closest winning margin was 55 sec. in 1964 when Jacques Anquetil, the only five-time winner, beat Raymond Poulidor (Fr.). The highest average speed was 23.182 mph by Anquetil, who won in 114 hr. 31 min. 54 sec. in 1962.

Olympic titles are regarded as world championships (see table in the article OLYMPIC GAMES). European championships were started in 1921, the winners being virtually champions of the world, but this event was not styled "World Championship" until 1937.

\*The championship, not being part of the Olympic Games until 1960, was also held: 1948 at The Hague, winner Denmark; 1952 at Copenhagen, winner Hungary; 1956 at London, winner U.S.S.R.

**CASTING.** World records are recognized by the International Casting Federation. The World Championship is awarded to the competitor having the most points upon conclusion of the ten

official accuracy and distance events in bait casting, fly casting, and spin casting. The first world championships under International Casting Federation Rules were held in Kiel, Ger., in 1957.

### World Records

Official Event	Record Holders	Record	Year
No. 1. Skish fly accuracy	G. Schop, Nor.; A. Kolseth, Nor.; S. Scheen, Nor.; J. Daubry, Fr.; J. Tarantino, U.S.	100 points	1957
No. 2. Fly distance and accuracy	O. Soderblom, Swed.	84.95 points	1965
No. 3. Fly distance single handed	R. Fredrickson, Swed. W. Vieser, Switz.	56.85 m. average 59.68 m. long cast	1964
No. 4. Fly distance two handed	J. Kolseth, Nor. J. Kolseth, Nor.	62.49 m. average 65.62 m. long cast	1961
No. 5. Skish bait accuracy, revolving spool, $\frac{1}{8}$ oz.	U. Janson, Swed.	96 points	1964
No. 6. Skish bait accuracy, spinning, $\frac{1}{8}$ oz.	U. Janson, Swed.	90 points	1964
No. 7. Bait distance, revolving spool, $\frac{1}{8}$ oz.	N. Oinert, Swed. N. Oinert, Swed.	103.12 m. average 103.98 m. long cast	1964
No. 8. Bait distance, spinning, $\frac{1}{8}$ oz.	K. Rosenstrom, Den. K. Rosenstrom, Den.	88.41 m. average 92.33 m. long cast	1965
No. 9. Bait distance, revolving spool, single handed, $\frac{1}{8}$ oz.	R. Fredrickson, Swed. R. Fredrickson, Swed.	137.20 m. average 144.36 m. long cast	1966
No. 10. Bait distance, spinning, 30 g., double handed.	N. Oinert, Swed. M. Gregory, U.S.	152.71 m. average 160.50 m. long cast	1964

(LEFT) A PASS INTERCEPTION BY A DEFENSIVE PLAYER WAS THE KEY PLAY IN ILLINOIS'S 40-7 VICTORY OVER STANFORD (ROSE BOWL, 1952). (CENTRE) A CHARGING GEORGIA TAILBACK DIVES OVER SOUTHERN METHODIST UNIVERSITY DEFENSIVE LINEMEN TO GAIN FOUR YARDS. SUCH STEADY GAINS GAVE GEORGIA A 24-9 WIN (COTTON BOWL, 1966). (RIGHT) A GOAL LINE FUMBLE MOMENTARILY DISRUPTS THE GEORGIA TECH OFFENSE BUT TECH RECOVERED TO BEAT MISSISSIPPI 24-7 (SUGAR BOWL, 1953)

U. P. I. COMPIX

**U.S. College Football Unofficial National Champions.**

The team selected each year by the Associated Press poll of sports writers and the United Press International poll of football coaches is popularly accepted as the unofficial national champion. The AP poll began in 1936 and the UPI poll in 1950; where the polls designated different teams, both are listed. Prior to the polls, from 1924 to 1936, the Rissman and Knute Rockne trophies symbolized the championship.

1924	Notre Dame	1946	Notre Dame
1925	Dartmouth	1947	Notre Dame
1926	Stanford	1948	Michigan
1927	Illinois	1949	Notre Dame
1928	S. California	1950	Oklahoma
1929	Notre Dame	1951	Tennessee
1930	Notre Dame	1952	Michigan State
1931	S. California	1953	Maryland
1932	Michigan	1954	Ohio State, UCLA
1933	Michigan	1955	Oklahoma
1934	Minnesota	1956	Oklahoma
1935	SMU	1957	Auburn, Ohio State
1936	Minnesota	1958	LSU
1937	Pittsburgh	1959	Syracuse
1938	TCU	1960	Minnesota
1939	Texas A & M	1961	Alabama
1940	Minnesota	1962	S. California
1941	Minnesota	1963	Texas
1942	Ohio State	1964	Alabama
1943	Notre Dame	1965	Alabama, Michigan State
1944	Army	1966	Notre Dame
1945	Army		

**U.S. College National Ratings.** The most successful major teams since 1936, according to the ratings produced by the press association polls, have been Notre Dame and Oklahoma. Counting 10 points for each season-end first-place rating, 9 for second, and so on, the Irish have accumulated 127 points, the Sooners 94, with the rest far behind:

1. Notre Dame	127	9. Army	61
2. Oklahoma	94	10. Minnesota	57
3. Alabama	81	11. LSU	52
4. Michigan	74	12. UCLA	52
5. Michigan State	72	13. Mississippi	50
6. Ohio State	68	14. Navy	50
7. Tennessee	67	15. S. Calif.	40
8. Texas	64	16. Georgia Tech.	39

1966	Saskatchewan Roughriders

\*No games 1916-19, East-West Playoff began in 1921.

**RUGBY UNION FOOTBALL.** The game, for amateurs only, is organized internationally by the International Rugby Union Football Board, which has seven members: England, Ireland, Scotland, Wales, Australia, New Zealand, and South Africa.

The game is organized in Europe by the International Amateur Rugby Federation (FIRA), which has ten members including France. France also plays international matches against the seven International Board countries.

### Complete Win-Loss Record of International (or Test) Matches\* 1871 to 1966

	England		Scotland		Ireland		Wales		British Isles	South Africa		New Zealand		Australia		France
England	—		38	14	46	7	32	10	—	0	1	1	0	1	0	27
Scotland	29	14	—		41	3	31	2	—	2	0	0	1	1	0	19
Ireland	25	7	33	3	—		23	4	—	1	0	0	0	1	0	19
Wales	29	10	37	2	42	4	—		—	0	0	3	0	3	0	28
British Isles†	—		—		—		—		—	10	2	2	2	2	0	—
South Africa	4	1	5	0	6	0	6	0	14	2	—	13	2	14	0	3
New Zealand	6	0	3	1	5	0	2	0	16	2	11	—	2	37	3	6
Australia	3	0	1	0	1	0	1	0	2	0	7	13	3	—	—	0
France	10	4	15	2	17	2	10	1	—	2	2	1	0	3	0	—

\*Reading across, the first figure is the all-time number of wins and the second the number of drawn matches against a given opponent. The number of losses to any opponent can be ascertained by reading downward.

†The British Isles ("British Lions") is a combined team from the four "Home Unions" (England, Ireland, Scotland, and Wales).

## World Cup Competition

Year	Place	Result
1954	Paris, Fr.	England 16 France 12
1957	Sydney, Austr.	New Zealand 29 England 21
1960	England	England 66 Australia 37

### Test Matches

The three principal Test-match series stand as follows:

England versus Australia (instituted 1909)  
 Played 76: England 44, Australia 28, 4 draws

England versus New Zealand (instituted 1908)  
 Played 47: England 31, New Zealand 15, 1 draw

England versus France (instituted 1957)  
 Played 20: England 12, France 6, 2 draws

MARVIN WARD, TWICE U.S. AMATEUR GOLF CHAMPION, TEEING OFF IN  
THE 1939 TOURNAMENT FINALS. WARD ALSO WON THE TITLE IN 1941

**GOLF.** The most important championships in golf have been The Open and Amateur (British) and the U.S. Open, Amateur, Professional (PGA), and Masters. International two-man team competition by professionals for the Canada Cup was inaugurated in 1953; and the World's Amateur Golf Council Eisenhower Cup tournament was inaugurated in 1958. Competition between teams representing the United States and the United Kingdom for the

Walker Cup (amateur) began in 1922, and for the Ryder Cup (professional) in 1927. The premier events in women's golf are the U.S. Women's Open and Women's Amateur and the British Women's Amateur. International team competition for women includes the Curtis Cup for U.S. and British amateurs since 1932, and the World Women's Amateur Team Championships instituted in 1964. For historic and other details *see* the article GOLF.

EASTFOTO

**HIGHLAND GAMES.** Highland Games became established as sporting events in 1848 when Queen Victoria took up residence in the Highlands of Scotland. The present-day program usually embraces track and field athletics (amateur or professional), highland dancing in costume, tug of war, piping contests, wrestling, and sometimes also cycling events and sheep trials.

The event peculiar to Highland gatherings is throwing the caber (earliest mention 1862). The great Braemar Caber (21 ft. long and 230 lb.) defied all comers until tossed in September 1951 by George Clark (Scotland). See further the articles CABER TOSSING; HIGHLAND GAMES.

**HOCKEY, FIELD.** The only world championships for this strictly amateur game are in the Olympic Games. Olympic tournaments were held in 1908, 1920, and since 1928 (see the article OLYMPIC GAMES).

**FIM Road Racing World Championships.** These championships, established in 1949, are staged for machines of engine capacity of 125, 250, 350, and 500 cc. and also for a sidecar event. The championships for the 500-cc. class are listed below.

Year	Champion; Country	Machine
1949	W. A. Lomas; U.K.	Norton
1950	V. Masetti; It.	Norton
1951	G. E. Duke; U.K.	Norton
1952	V. Masetti; It.	Gilera
1953	G. E. Duke; U.K.	Gilera
1954	G. E. Duke; U.K.	Gilera
1955	G. E. Duke; U.K.	Gilera
1956	J. Surtees; U.K.	M.V.
1957	L. Liberati; It.	Gilera
1958	J. Surtees; U.K.	M.V.
1959	J. Surtees; U.K.	M.V.
1960	J. Surtees; U.K.	M.V.
1961	G. Hocking; Rhod.	M.V.
1962	S. M. B. Hailwood; U.K.	M.V.
1963	S. M. B. Hailwood; U.K.	M.V.
1964	S. M. B. Hailwood; U.K.	M.V.
1965	S. M. B. Hailwood; U.K.	M.V.
1966	G. Agostini; It.	M.V.

**Speedway.** The sport, usually limited to 4 starters, is run over 4 laps on cinder or dirt circuits. Speedway originated in Australia in 1927 and was introduced into Europe in 1928.

## World Champions

1936	L. van Praag; Austr.
1937	J. Milne; U.S.
1938	B. Wilkinson; Austr.
1939*	
1949	T. Price; U.K.
1950	F. Wales; U.K.
1951	J. Young; Austr.
1952	J. Young; Austr.
1953	F. Williams; U.K.
1954	R. Moore; N.Z.
1955	P. Craven; U.K.
1956	O. Fundin; Swed.
1957	B. Briggs; N.Z.
1958	B. Briggs; N.Z.
1959	R. Moore; N.Z.
1960	O. Fundin; Swed.
1961	O. Fundin; Swed.
1962	P. Craven; U.K.
1963	O. Fundin; Swed.
1964	B. Briggs; N.Z.
1965	B. Knutsson; Swed.
1966	B. Briggs; N.Z.

\*Not completed because of World War II.

**PIGEON RACING.** The invention of the electric telegraph in the 1840s resulted in the disposal of many lofts of trained homing or racing pigeons (the rock dove *Columba livia*) and the start of pigeon racing as sport (see also the article PIGEON FLYING).

### RECORDS

#### Distance

Homing Flights, about 7,000 mi.  
Ichabo Islands, W. Af., to Nine Elms, London, U.K., 55 days: April 8-June 1, 1845 (bird owned by the 1st duke of Wellington)  
Saigon, Indochina (S. Vietnam), to Arras, Fr., 8 days: Sept. 8-15, 1931

#### Race Speed

96.29 mph  
C. Copelands' winner of the Maree, South Australia Homing Pigeon Association race, 1947

#### 24-hour Record

751 mi. (flying time 15 hr. 52 min.)  
Edfelt and Wahistrom's winner of the Lulea-Ystrad, Swed., race, 1951

MILLER SERVICES LTD.

S. A. MACKENZIE (AUSTR.), WINNER OF THE DIAMOND CHALLENGE SCULLS AT HENLEY-ON-THAMES, ENG., 1957-62, CROSSING THE FINISH LINE IN 1962

**University Boat Race.** The University Boat Race between Eights from Oxford and Cambridge universities was instituted on June 10, 1829. The record time for the course of 4 mi. 374 yd. from Putney to Mortlake on the River Thames is 17 min. 50.0 sec. by Cambridge in 1948. The results up to the 112th race in 1966 have been Cambridge 61 wins, Oxford 50 wins, and one dead heat (in 1877).

**The Diamond Challenge Sculls.** The annual single sculls event in the regatta at Henley-on-Thames, Oxfordshire, Eng., instituted 1844, is open to the world. The course is 1 mi. 550 yd.

## SHOOTING

## Official World Records

Event	Name; Country	Score	Place	Year
Free rifle 300 m. 3 X 40 shots	G. L. Anderson; U.S.	1,153	Tokyo, Jap.	1964
Small-bore rifle 50 m. 3 X 40 shots	L. W. Wigger, Jr.; U.S.	1,164	Tokyo, Jap.	1964
Service rifle 300 m. 3 X 20 shots	A. Tilik; U.S.S.R.	555	Moscow, U.S.S.R.	1958
Free pistol 50 m. 60 shots	A. Jassinskiy; U.S.S.R.	566	Bucharest, Rum.	1955
Rapid free pistol 25 m. 60 shots	A. Kropotkin; U.S.S.R.	595	Stockholm, Swed.	1963
Centre-fire pistol 25 m.	T. D. Smith III; U.S.	597	São Paulo, Braz.	1963
Skeet 200 (possible)	N. Durnev; U.S.S.R.	200	Cairo, U.A.R.	1962

The (British) National Rifle Association (instituted 1860) annual Queen's (or King's) prize shoot at Bisley, Eng., over distances from 200 to 1,000 yd., is the world's premier rifle shooting event. The possible top score is 300. The record score is 292 by Capt. C. H. Vernon on July 15-16, 1927.

**SHOW JUMPING.** The Olympic Games (since 1900, except 1908) provide the only world championships. For results see the article OLYMPIC GAMES.

\*No competition.

## SWIMMING

**WORLD RECORDS**—distances recognized by the International Swimming Federation (Fédération Internationale de Natation Amateur). Only performances set in 50-m. or 55-yd. pools are recognized as world records (since May 1, 1957). Where the time at a "yards" distance in a 55-yd. pool is faster than the world record for the "metric" equivalent, it may be ratified as a "metres" record also. "Yards" records cannot be set in a 50-m. pool.

Men				
Freestyle Distance	Time min.:sec.	Name; Country	Place	Date
100 m.	52.9	A. Gottvalles; Fr.	Budapest, Hung.	Sept. 13, 1964

\*Swaythling Cup. †Corbillon Cup. ‡No competition.

**TENNIS.** The Davis Cup for international competition was inaugurated in 1900 (see the article *TENNIS: Lawn Tennis*). The winning team in the zone and interzone challenge rounds meets the incumbent holder, all competitions consisting of four singles and one doubles match. The four major national championships—the All England (Wimbledon), U.S., French, and Australian—are contested by representative fields of the world's leading amateurs.

## TRACK AND FIELD SPORTS

**WORLD RECORDS (Outdoor) Men.** The complete list of World Records for the 54 scheduled men's track and field events passed by the International Amateur Athletic Federation as of June 30, 1967. For Olympic records and world records set in the Olympics see the article OLYMPIC GAMES. Indoor records, more correctly "best performances," are not sanctioned by any international body.

\*Awaiting ratification.

†No new records for this version of this event have been recognized since October 1960.

‡A British Commonwealth team of A. Blue (Aust.), G. E. Kerr (Jam.), T. S. Farrell (U.K.), and P. G. Snell (N.Z.) recorded a time of 7:18.0 at the White City, London, on Sept. 14, 1960, but, being a composite team, the performance cannot be accepted by the IAAF. A United Kingdom national team (G. D. Grant, G. P. M. Varah, C. S. Carter, and J. P. Boulter) recorded 7:14.6 at the Crystal Palace, London, on June 22, 1966, but lap times were illegally communicated to the runners.

## Decathlon (1962 Scoring Tables)

8,089 points	Yang Chuan-kwang; Formosa	Walnut, U.S.	April 27-28, 1963
1st day: 100 m. 10.7 sec., long jump 23'6¼", shot 43'4¼", high jump 6'3½", 400 m. 47.7 sec.			
2nd day: 110 m. hurdles 14.0 sec., discus 134'6", pole vault 15'10½", javelin 235'5", 1,500 m. 5:02.4			
8,234 points*	B. Toomey; U.S.	Salina, U.S.	July 2-3, 1966
1st day: 100 m. 10.3 sec., long jump 25'6", shot 45'8¼", high jump 6'4½", 400 m. 47.3 sec.			
2nd day: 110 m. hurdles 14.8 sec., discus 147'5½", pole vault 13'0", javelin 198'11", 1,500 m. 4:30.0			

Note: P. R. Mulkey, U.S., achieved a score of 8,155 points in an unsanctioned meet at Memphis, U.S., on June 16-17, 1961.

\*Awaiting ratification.

†Rounded from metric equivalent: actual measurement 27 ft. 4¼ in. (8.35 m.).

WALTER LOOSE, JR. FOR "SPORTS ILLUSTRATED," © TIME INC.

RALPH BOSTON (U.S.) SETTING A WORLD RECORD OF 27 FT. 5 IN. IN THE LONG JUMP AT MODESTO, CALIF., 1965

**The Marathon.** There is no official Marathon record because of the varying severity of the courses. The best time over 26 mi. 385 yd. (standardized in 1924) is 2 hr. 12 min. 00 sec. by M. Shigematsu, age 24, of Japan, on the point-to-point course from the grounds of Windsor Castle, in New Windsor, Berkshire, to the Polytechnic Stadium, Chiswick, Greater London, on June 12, 1965. The best time for an "out and home" course is 2 hr. 12 min. 11.2 sec. by Abebe Bikila of Ethiopia, in the 1964 Olympic Games (q.v.) in Tokyo.

**Cross-Country.** Like the Marathon, there is no official record for Cross-Country running because of the varying severity of the courses. Cross-Country was an Olympic sport from 1912 to 1924 (see table in the article OLYMPIC GAMES). For history of the sport see the article RUNNING.

Year	Individual winner; Country	Team winner
1965	J. Fayolle; Fr.	United Kingdom
1966	B. El Ghazi; Mor.	United Kingdom

\*No competition.

For Olympic class winners see table in the article OLYMPIC GAMES.

**SPORTS (ARTICLES ON).** A universal form of recreation, sports are also one of the great expressions of the aspiration to excel. The victories of athletes were sung by the great poets of classical Greece. Many of *Encyclopædia Britannica's* articles on sports discuss their development in the context of social history. Among the articles in this group are BASEBALL; BOWLING; BOXING; CRICKET; FOOTBALL; GOLF; and WRESTLING.

For records of all major sports see **SPORTING RECORD**. **TRACK AND FIELD SPORTS** is supplemented by articles on individual events, such as DISCUS THROWING; POLE VAULTING; SHOT-PUT; etc. The history, development and present status of the major winter sports are covered in separate articles such as BOBSLED-DING; CURLING; ICE HOCKEY; and SKIING.

Some of the aquatic sports articles are BOATING; CANOE; MOTORBOAT; ROWING; SKIN DIVING; SWIMMING; WATER POLO.

Among the articles dealing with racing sports are AUTOMOBILE RACING; CYCLING; HORSE RACING AND BREEDING; MOTORCYCLING; RUNNING; and WALKING.

Among the court games to which articles are devoted are BADMINTON; DECK TENNIS; RACKETS; and TENNIS. Additional articles on games played with a ball include BASKETBALL; FIVES; HANDBALL; JAI ALAI; LACROSSE; ROUNDERS.

A general view of the sports that have been popular among or adapted to the needs of children is given in **CHILDREN'S GAMES AND SPORTS**.

In some sports of almost universal interest, man's strength and resourcefulness are matched against other forms of life or against forces of nature. Articles dealing with these activities include FISHING; HUNTING; and MOUNTAINEERING. **TOURNAMENT** deals with the great sport of medieval chivalry. Sports of antiquity that are still practised are treated in ARCHERY; FALCONRY; and FENCING.

**GAMES, CLASSICAL**, describes the athletic festivals that played an important part in the life of ancient Greece and Rome. Articles dealing with modern sports festivals include **BRITISH COMMONWEALTH GAMES**; **HIGHLAND GAMES**; **OLYMPIC GAMES**; and **PAN-AMERICAN GAMES**.

**AMATEUR** traces the ancient distinction between the amateur and professional and describes the contemporary rules governing amateur standing. **GYMNASTICS** discusses the evolution of the art, the types of exercises, and the skills involved. **GYMNASIUM** deals with types of equipment. The function of gymnastics in educational programs is discussed in **PHYSICAL EDUCATION**.

For articles on nonathletic games, such as cards and board games, see **GAMES (ARTICLES ON)**.

**SPORTS, THE BOOK OF**, or, more properly, the **DECLARATION OF SPORTS**, an order issued by James I in 1617 on the recommendation of Thomas Morton, bishop of Chester, for use in Lancashire, where the king, on his return from Scotland, found a conflict on the subject of Sunday amusements between the Puritans and the gentry, many of whom were Roman Catholics. Permission was given for dancing, archery, leaping, vaulting, and other harmless recreations, and for "having of May games, Whitsun ales and morris dances, and the setting up of May-poles and other sports therewith used, so as the same may be had in due and convenient time without impediment or neglect of divine service, and that women shall have leave to carry rushes to church for the decorating of it." On the other hand, "bear and bull-baiting, interludes, and (at all times in the meane sort of people by law prohibited) bowling" were not to be permitted on Sunday. In 1618 James transmitted orders to the clergy of the whole of England to read the declaration from the pulpit, but so strong was the Puritan opposition that he prudently withdrew his command. In 1633 Charles I not only directed the republication of his father's declaration but insisted upon the reading of it by the clergy. Many of the clergy were punished for refusing to obey the injunction. With the fall of William Laud, archbishop of Canterbury, who had supported the republication, Puritan prohibitions against sports and games on the Sabbath again prevailed.

**SPOTSWOOD, ALEXANDER** (1676-1740), American colonial governor, was born of Scottish parents in Tangier, Africa, in 1676. Commissioned an ensign at the age of 17, he served under

the Duke of Marlborough in the War of the Spanish Succession as a lieutenant colonel and was wounded at Blenheim. He was appointed lieutenant governor of Virginia in 1710 but exercised full authority because the nominal governor never visited the colony; his term as governor ended in September 1722, but he remained in Virginia, living near ironworks that he had established in Germanna, a settlement of Germans in Spotsylvania County (named in his honour). From 1730 to 1739 he served as deputy postmaster-general of the colonies.

Spotswood was one of the first representatives of the British government in America who fully appreciated the value of the western territory. As governor he recommended the establishment of a Virginia company to carry on trade with the Indians; he urged upon the provincial government and also upon the British authorities the wisdom of constructing forts along the frontier; and he personally organized and conducted in 1716 an exploring expedition into the Shenandoah Valley.

Spotswood developed the iron industry in Virginia and promoted the religious education of the Indians. He died at Annapolis, Md., June 7, 1740. (R. M. Br.)

**SPOTSYLVANIA**, a county in Virginia, U.S., midway between Washington, D.C., and Richmond, Va.; the scene of four major battles during the American Civil War (*q.v.*). At Fredericksburg (Dec. 13, 1862) and Chancellorsville (May 1-3, 1863) Confederate Gen. R. E. Lee inflicted severe defeats on Union armies attempting to move on Richmond. The Wilderness (May 5-6, 1864) and Spotsylvania Courthouse (May 9-20, 1864) were costly but indecisive battles in Union Gen. U. S. Grant's successful campaign of that year. (See also **CHANCELLORSVILLE**; **FREDERICKSBURG**.)

The population of the county in 1960 was 13,819; its area is 409 sq.mi. About half of the area is devoted to agriculture, much of it dairy farming. Manufacturing, mainly of lumber and lumber products, is the principal employer of the labour force. First settled in the late 17th century, the county was formed in 1720 and named for Alexander Spotswood, then governor of Virginia. (M. Br.)

**SPOTTED FEVER**: see **ROCKY MOUNTAIN SPOTTED FEVER** AND **OTHER SPOTTED FEVERS**.

**SPOTTISWOODE, JOHN** (1565-1639), archbishop of St. Andrews and a historian of the Scottish Church, was the eldest son of John Spottiswoode. Educated at Glasgow University, he succeeded his father as parson of Calder in 1583. He attended Ludovic, duke of Lennox, as his chaplain, in an embassy (1601-03) to the French court and accompanied James VI of Scotland to England in 1603 on his accession to the English throne as James I. He was nominated to the see of Glasgow in the same year. At that time the Scottish episcopate was mainly titular, but the bishops' powers were gradually restored, and in 1610 Spottiswoode presided as moderator over the General Assembly which accepted the full restoration of episcopacy in Scotland. He was consecrated in London (October) and was made archbishop of St. Andrews in 1615. In 1618 he procured the sanction of the General Assembly to the Five Articles of Perth. He crowned Charles I at Holyrood in 1633. A member of the Scottish Privy Council since May 1605, he was chancellor of Scotland from 1635 to 1638.

Spottiswoode consistently favoured a moderate church policy and did not wholly approve of Charles's innovations in worship and discipline. A spectator at the riot in St. Giles Cathedral, Edinburgh, on July 23, 1637, which resulted from the introduction of the revised prayer book, he tried to avoid disaster by concessions but on hearing of the signing of the National Covenant (February 1638) perceived that "now all that we have been doing these 30 years past is thrown down at once." He escaped to Newcastle and was deposed by the General Assembly on Dec. 13, on trivial charges. He died in London on Nov. 26, 1639, and was buried in Westminster Abbey. His most important work, *The History of the Church of Scotland . . .* (1655), written at the request of James, covers the period between the years 203 and 1625.

See the account of his life in the first edition of his *History* and in that published by the Spottiswoode Society, 3 vol. (1847-51). (Gn. D.)

**SPRAGUE, FRANK JULIAN** (1857-1934), U.S. engineer known as the father of electric traction, was born in Milford, Conn., July 25, 1857. He attended the U.S. Naval Academy, graduating in 1878. Resigning his naval commission in 1883, he joined the staff of Thomas A. Edison, but a year later he set up his own shop, where he subsequently devised a "constant-speed" electric motor to operate on commercial circuits. This brought him a contract to provide equipment for the Union Passenger Railway of Richmond, Va. (see **ELECTRIC TRACTION**). Cars equipped with his motors were in operation early in 1888, and their marked success brought 113 orders to equip electric railways in U.S. and European cities. In 1895 he developed a multiple-unit control system whereby a string of motorized cars could be operated by a master switch, with the wheels of each car acting as a driving force. He died in New York City, Oct. 25, 1934.

**SPRAY GUN AND AIR BRUSH** are painting tools that utilize compressed air to atomize a liquid into a controlled pattern. Spraying is the act of breaking up or atomizing a liquid into a multitude of tiny droplets, which are formed when a liquid is drawn into a slender stream or thin film. Since it is not usually practical to form a stream of liquid thin enough to produce a fine spray, it is necessary to utilize a device such as the spray nozzle.

The spray nozzle is the heart of the spray gun and air brush and operates by impinging high-velocity turbulent air on the surface of filaments or films of liquid which when stretched to a thin film collapses to droplets. This action produces a wide range of particle sizes.

An air brush resembles a pencil and is used by photographers and commercial artists for applying colour and shading to drawings, prints, and photographs and to accentuate highlights and supply background to films. The more complex spray gun, developed originally from the air brush, is used for less delicate work and requires less skill to operate. Lacquers, paints, varnishes, shellac, and other finishes for manufactured articles are applied with spray guns that are designed to be simple to operate, adjust, and clean.

Various types and combinations of spray guns are available for different applications. Portable equipment is used for maintenance painting of both new and old construction. Automobiles, furniture, and appliances are usually finished under clean, rigidly controlled working conditions with stationary equipment. The finishes may be supplied to the gun by gravity from an overhead reservoir (for low-viscosity lacquers), by suction from a container that is part of the spray gun (for small work and where frequent colour changes occur), or by pressure in a mass-production operation. An adequate supply of dry air is provided by auxiliary equipment, such as compressors, air-reducing valves, oil and water separators, and flexible hose. (P. HE.)

**SPRAYS AND DUSTS IN AGRICULTURE.** Spraying, dusting, and fumigating are the standard methods of applying the pest-control chemicals and some of the other chemical compounds that are of increasing importance in agriculture. In spraying, the chemicals to be applied are dissolved or suspended in water, or less commonly in a petroleum carrier. The mixture is then applied as a fine mist spray to the plants, animals, soils, or products to be treated. As an alternative method, dry, finely powdered chemicals may be mixed with an inert carrier and applied with some type of blower. Dry granular materials also have been used instead of dusts for purposes in which adequate coverage can be obtained by this means. In fumigation, gases or the vapours of volatile compounds are held in contact with the materials to be treated—grain in a tight bin, for example.

The development of more and more effective sprays and dusts and their increasingly widespread use in agriculture have prompted concern among biologists and others that man may disrupt nature and endanger his food supply and his own health (see **PEST CONTROL**).

#### SPRAYING AND DUSTING MACHINERY

A great variety of equipment is available for applying organic and inorganic substances in solution, suspension, or dust form to

combat insect pests and plant diseases of field, garden, and orchard crops, and to control weeds or other unwanted vegetation. Spraying and dusting are also used for defoliation before harvest, especially for cotton; for applying mineral fertilizers under special conditions; for thinning fruit with blossom-killing chemicals; and for applying various hormone materials to plants to control fruit set, fruit drop, etc. The term sprayer is applied to devices that dispense solutions, and the term duster to those that apply chemicals in the form of dry, finely divided powders or dusts.

**Spraying Equipment.**—Sprayers differ greatly in size and capacity, source of power, and other characteristics. They commonly utilize pressure produced by pumps to force the spray solution through specially designed nozzles that break it up into mists, thus covering a maximum percentage of the plant surface with protecting chemicals or reaching a maximum number of insects with contact insecticides. Liquid pumps are commonly used to handle the spray directly, but air pumps that develop pressure in the liquid container, forcing the liquid through the nozzles, are used in some hand sprayers and in special situations. Cylinders of compressed carbon dioxide or other gases are sometimes used as a source of pressure, and refillable aerosol bombs, similar to but larger than those employed for household sprays, may be used for spraying in greenhouses or gardens. Pressure in these bombs is maintained by the evaporation of a volatile solvent, such as Freon.

Nozzles for spraying are commonly of two types. One produces a cone of spray for medium and close applications, and the other produces under high pressure a comparatively solid stream of liquid that breaks up at a considerable distance. Spray guns can be adjusted quickly between these two types. A third and less common type of nozzle produces a flat fan of spray. The solid-stream nozzle is generally used singly for spraying tall trees. The cone type may be used singly on small sprayers or in groups, either on a hand-controlled rod with a single cutoff or on a mounted boom. Grape and hop sprayers may use vertical booms with several nozzles on each side of the sprayer. Row-crop sprayers commonly have a horizontal boom with nozzles adjusted to row widths. One nozzle is mounted above the row; frequently there is also one on each side of the row, angled upward and mounted on drop pipes.

Weed-control sprayers may use fan-type nozzles on a straight boom for controlling weeds in small grain, or drop pipes with carefully directed nozzles for spraying under corn (maize) or other tall row crops. In the concentrate or air-type sprayer the nozzles are mounted in the air stream from a motor-driven fan. Air from the fan carries and distributes the fine spray produced by the nozzles.

**Manual Sprayers.**—The simplest form of household or garden sprayer consists of a bicycle-type air pump with a small container attached, and an atomizer nozzle. The knapsack sprayer, as its name implies, is carried on the back of the operator, pressure usually being provided through a diaphragm pump that also actuates an agitator.

In the compressed-air sprayer, pressure is built up with a plunger-type air pump housed in the container with the solution and air. Typical manual sprayers have capacities ranging from 1½ to 4 gal. Of these same types but of larger capacity are the wheelbarrow and barrel sprayers.

**Power Sprayers.**—There are three types of power sprayers: those powered with an engine mounted on a frame with the tank, those powered through a power takeoff from truck or tractor motor, and those deriving their power from a traction drive. With the first two the same type of assembly may be used. This consists essentially of a single-acting, plunger-type, reciprocating pump (usually two or three cylinder), a strainer to remove sediment that might clog the nozzles, a pressure regulator that also acts as a safety valve, a metal or wooden tank containing the liquid and an agitator for stirring it, and such accessories as pressure gauges, cutoff valves, and, frequently, air chambers. The pumps obtain their reciprocating motion most commonly from either a crankshaft and connecting rods, eccentric and connecting rods, or a Scotch-yoke (slotted crosshead) assembly and are available in a wide range of sizes and capacities, with pressures up to 1,000 lb.

per sq. in. Corrosion-resistant valve seats and ball-type valves, usually of hardened stainless steel, are used in the pumps and two types of plunger-cylinder combination—the plunger cup, where the cup is fastened to and moves with the plunger, rubbing against the cylinder wall, which is usually coated with porcelain, and the outside-packing type, in which a stainless-steel plunger works back and forth in the stationary packing lining the cylinder wall. The engine-powered sprayer and its engine may be mounted on skids for semistationary work and supplied with portable pipelines to conduct the solution; it may be fixed as a stationary plant and powered either with an engine or electric motor, in which case the conducting pipes are buried in the ground and lead to risers at strategic points for attachment of the spraying equipment; or it may be mounted on a motor truck or on a two- or four-wheel trailer and driven either by its own engine or by a power takeoff connection from the tractor pulling it, or from the transmission case of the truck transporting it.

Occasionally the whole spraying outfit may be mounted on the tractor. Pneumatic tires are generally considered desirable on spray-equipment trailers. Traction-driven sprayers derive their power from the transport wheels, and their use is limited largely to row crops. In most instances the power takeoff or auxiliary-engine drive is more suitable.

**Concentrate or Air Sprayers.**—These sprayers, which are also called speed sprayers, are power sprayers with a motor-driven fan that spreads the spray, usually in a concentrated solution at low volume, in a stream of high-velocity air. They vary in size from sprayers with a capacity of one or a few gallons that are carried or wheelbarrow-mounted to giant orchard or row-crop sprayers, operated by one man, that can cover 100 to 200 ac. of crop per day.

The use of an air stream makes it possible to reduce the spray volume to as little as one gallon an acre and thus make great savings in transportation, a factor of considerable importance in rough terrain or where water is scarce. Chemicals are dissolved in water or in especially purified oils of the fuel-oil boiling-point range. (Ordinary fuel oils should not be used, since the aromatic compounds they contain are toxic to plants.) The small units are suitable where labour is inexpensive or where the use of large machinery is impractical. The largest units are used by contract sprayers in level areas of extensive culture. Crops sprayed vary from tea and coffee to bananas and orchard crops of all types. Row-crop concentrate sprayers are designed to force a beam of chemical-carrying mist across the field for 50 to 100 ft. and are adjustable to compensate for wind and uneven land surface.

**Dusting Equipment.**—Dusters for applying insecticides and fungicides make use of an air blast produced by means of a fan or plunger-type air pump, which blows the dust into a discharge pipe fitted with a straight-tube or fan-shaped nozzle. The many makes and models of dusters are of four types: (1) hand operated, in which the air pressure is built up with a plunger pump or with a crank-operated fan; (2) the traction machine, in which the power for operating is taken from the ground wheels through chains or gears; (3) the power duster (horse or tractor drawn), operated by an auxiliary gasoline engine and suitable for single-spout orchard dusting, or (by changing to a multiple-nozzle unit) useful in row-crop dusting; and (4) the tractor-power duster, mounted on the tractor and driven through the tractor-power takeoff. The power and traction types consist essentially of a hopper, agitator, feed control, blower fan, mixing chamber, discharge tubes, and nozzle or nozzles. Dusters are convenient for gardens or small areas where a few plants must be treated at frequent intervals; concentrate sprayers are generally more suitable for fieldwork.

Granular, dry mixtures have been used where complete coverage is unimportant, as in distributing grasshopper bait and some weed-control chemicals. Granulation permits a wider distribution of dry material with minimum drifting.

**Airplane Spraying and Dusting.**—In the Cotton Belt of the United States, dusting of the plants by means of airplanes has proved economical. The work is done during daylight, generally in the early morning or late afternoons, when it is considered safest to fly at the necessary low altitudes, and when the moisture on the plants causes the dust particles to adhere better. Commercial

firms usually do the dusting on a per-acre basis and commonly dust at a rate of 350 ac. or more of cotton per hour. Dusting by airplanes has also been employed in California to control insect pests and plant diseases attacking a number of fruit, nut, vegetable, and small-grain crops. Airplane spraying of weed-killer concentrates has become important in grain-growing regions, and brush in rough grazing land often is most economically controlled by spraying from the air.

(R. B. G.; W. E. Ls.)

## SPRAYS AND DUSTS

Sprays and dusts are used to control insect and fungus pests of plants; insects, such as lice and flies on animals; and weeds, by means of chemical weed killers or herbicides. They may also be used for such special purposes as applying mineral fertilizers, increasing or decreasing fruit set or delaying the dropping of nearly mature fruits, and for defoliation to facilitate the harvest of such plants as cotton.

Sprays have advantages over dusts in their ability to adhere to and spread over treated surfaces. Wetting agents or detergents are commonly added to spray mixtures to increase adhesion and wetting of waxy surfaces. Detergents decrease the tendency of water to collect in drops and permit the chemical solution to spread over a leaf in a very thin film, thus bringing the spray chemical into maximum contact with the fungi or insects to be controlled. Dusts can be lighter in weight per unit of active chemical and thus are better adapted for airplane application. They also drift through the foliage and reach leaves that might not be covered by spraying. After about 1950 there was a rapid increase in the use of air sprayers or "wet dusting." The use of a concentrated spray distributed in the air stream from a powerful fan combines many of the advantages of both spraying and dusting.

Fumigation (*q.v.*) may be used to control insects and some diseases in stored products or to control insects, such as wireworms and grubs, nematodes, and sometimes fungi and weeds in soil. The chemical may be applied as a gas or as a volatile liquid. Partial fumigation of the soil may be accomplished by applying the chemical in a spray or granular material and immediately working it into the soil. For more exacting work on small areas like seedbeds the treated soil is covered with a gastight canvas or plastic cover.

**Fungicidal Treatments.**—The practice of spraying plants to control plant diseases (*q.v.*) is said to have been discovered accidentally near Bordeaux, France, when a copper-lime mixture applied to grapes near a road to reduce pilfering was observed to control downy mildew, a serious disease of the grape plant. This spray, since known as Bordeaux mixture, remains a standard fungicide, although organic materials are replacing the older copper and sulfur sprays. Among the dozens of modern fungicides, several are especially valuable in general use: captan (trichloromethylthiocyclohexene-dicarboximide), an organic compound sold as a wettable powder, alone or in all-purpose mixtures, and used to treat seeds and bulbs or as a spray or dust on fruits, vegetables, and ornamentals for the control of a wide range of fungous diseases; ferbam (ferric dimethyldithiocarbamate), a wettable powder used in sprays and dusts, and as a soil drench to control damping-off diseases of seedling plants; and zineb (zinc ethylenebis-dithiocarbamate), a general purpose fungicide, particularly recommended for blights of tomato and potato and as a soil drench to control crown and root rots of vegetable and flower plants. In general these compounds control more diseases under more conditions and are less toxic to the treated plants than the older copper or sulfur sprays. Streptomycin, an antibiotic, has shown promising results in the control of bacterial plant diseases.

**Insecticidal Treatments.**—Formerly insecticides were limited primarily to arsenic compounds like Paris green and calcium and lead arsenates for chewing insects, nicotine for soft bodied, sucking insects, and oil and lime-sulfur for scale insects. Tobacco powders and infusions were used in Europe before 1800 and pyrethrum powders in Asia Minor at an unknown date. Paris green (copper aceto-arsenite) was used successfully against the potato beetle in Illinois in 1868 and was used against major apple insects a few years later. Calcium arsenate was the chief insecticide used on cotton from 1920 to 1945.

The compound popularly known as DDT (dichloro-diphenyl-trichloroethane) was among the first of a new group of organic insecticides that includes aldrin (hexachloro-hexahydro-endo, exo-dimethanonaphthalene), lindane (gamma isomer of benzene hexachloride), methoxychlor (trichloro-methoxyphenylethane), parathion (diethylnitrophenyl phosphorothioate), and many others. Most of these are chlorinated hydrocarbons. The organic phosphorus compounds, such as parathion, are among the most effective poisons but are exceedingly dangerous to operating personnel unless proper precautions are observed. Malathion (ethoxy-carbonyl-ethyl-dimethyl phosphorodithioate) shows most of the effectiveness of parathion and is much safer to use. This and other organic phosphorus insecticides have become increasingly important. (See also PEST CONTROL: *Chemical Control*.)

Arsenic compounds are toxic only when ingested by the insect. DDT is a nerve poison, and paralysis spreads from any part of the insect body that comes in contact with the chemical. It is, therefore, very effective when sprayed on surfaces over which the insects crawl. The initial popularity of DDT decreased with the discovery of the development of resistance in treated insect populations and with fear of human toxicity from accumulation of the compound as a result of eating contaminated foods. The tolerance for DDT contamination in milk was set at zero in the United States; that is, no use—such as spraying of dairy animals, their quarters, or their feed—that could result in the transmission of the compound to milk was permitted. Directions for control of garden insects specified that DDT should not be applied to foliage to be eaten or to other edible plant parts that cannot be washed thoroughly or peeled before eating. Malathion, applied not later than three days before harvest, or methoxychlor, not less than seven days before harvest, were the generally recommended insecticides for garden use.

As a rule both the organic fungicides and insecticides are sold as wettable powders for sprays, as dusts, or in emulsifiable, concentrated solutions. (See also ENTOMOLOGY: *Agricultural and Forest Entomology*.)

**Herbicide Treatments.**—Weed-killing chemicals are normally applied as sprays or as dry, granular formulations of compounds that act through the soil. Their use is a comparatively recent development, although ferrous sulfate and other compounds were used to control mustard and similar weeds in grainfields before 1900. Sodium chlorate was used in increasing volume as a nonselective herbicide after 1905, but the simultaneous discovery of 2,4-D (2,4-dichlorophenoxyacetic acid) in the United States and of MCPA (2-methyl-4-chlorophenoxyacetic acid) in England during World War II marked the beginning of the widespread use of herbicidal chemicals. These compounds may be essentially non-toxic to grains and grasses at rates that will kill most broadleaved weeds. (See also WEED: *Control of Weeds*.)

Herbicides may be classed as selective or sterilant. Ferrous sulfate is a selective herbicide for mustard in grain because it adheres to the leaves of the mustard but not to those of the grain. The compound 2,4-D is selective because of its greater toxicity for most broadleaved plants than for grasses, including grains. Trichloroacetic acid (TCA) is selectively toxic to grasses. Sodium chlorate is a general toxin, used to eradicate noxious perennial weeds at the cost of temporary soil sterility or to control all vegetation on railway roadbeds and similar areas. Chlorate is effective primarily as it is absorbed through the roots from the soil and should be applied so that rainfall or irrigation will carry it into the root zone. Rates of application vary from 1 or 2 to 10 or 12 lb. per sq.rd.

MCPA and 2,4-D may be translocated downward through the roots of perennial weeds. Rates, in contrast to those for chlorate, are commonly one-half to two pounds an acre, applied in a spray. The compound 2,4,5-T, 2,4-D with an extra chlorine in the 5-position, is slower in action and more effectively translocated than 2,4-D. It is preferred for controlling brush and some perennials. Great care is necessary when using any of these compounds near susceptible plants, as the slightest drift of the spray, or even the fumes, may cause injury.

The use of a special petroleum fraction known as Stoddard sol-

vent in weeding carrots and other members of the parsley family is a striking example of differential herbicidal action. These plants are resistant, while most others are killed by the spray. Other oils are used for various purposes. Moderately heavy oils high in aromatic compounds are useful on such surfaces as ditch banks and roadbeds.

**Miscellaneous Treatments.**—Soluble fertilizer materials may be applied in sprays, either to the soil when accurate distribution of small quantities is required, or to the leaves of the plants. Sprays are used extensively to apply iron or manganese to pine-apple leaves and less extensively to supply nitrogen—in the form of urea—to apple trees. Defoliant sprays and dusts are used to eliminate leaves from cotton and some other plants before machine harvesting. A cotton defoliant must cause the leaves to drop naturally rather than kill them, since the crumbled dead leaves reduce the grade of the lint. Cyanide dusts and dilute chlorate sprays are among the more successful treatments.

Both toxic compounds like sodium dinitro-*o*-cresylate and hormone-type sprays like naphthaleneacetic acid have been used to thin fruits when excessive crops are set. Dinitro kills a percentage of the young fruit and injures the foliage more or less extensively. Hormones cause embryo abortion in young fruits and accentuate natural drop. The same hormone compound may be used later to reduce preharvest drop of nearly mature fruit. Naphthaleneacetic compounds, dilute 2,4-D, or other hormone-type materials may be used to increase fruit set in tomatoes or beans, and to prevent sprouting of potatoes, or leaf and berry drop of holly in Christmas decorations. Wax emulsions are sprayed on nursery stock to reduce water loss during shipping and after planting. New uses for new chemicals, applied as sprays or dusts, are constantly being developed.

**BIBLIOGRAPHY.**—H. P. Smith, *Farm Machinery and Equipment* (1955), contains a good chapter on spraying and dusting equipment, as well as a consideration of related machinery; *Sprayer and Duster Manual*, published by the National Sprayer and Duster Association, Chicago, is a small manual with much useful information and is distributed free to interested persons; Texas Agricultural and Mechanical College, *Handbook of Aerial Application in Agriculture* (1956), covers dusting from the air. Many U.S. and other experiment stations have bulletins on spraying and dusting equipment. See also *Agricultural Engineers Handbook*, ed. by C. B. Richey (1961). "Insects and Diseases of Vegetables in the Home Garden," *Home and Garden Bulletin No. 46*, U.S. Department of Agriculture (1956) is an excellent brief reference; W. S. Hough and A. F. Mason, *Spraying, Dusting and Fumigating of Plants* (1951) presents a thorough discussion. See also L. L. Pyenson, *Elements of Plant Protection* (1951); *Pesticides in Tropical Agriculture*, published by the American Chemical Society (1955); D. E. H. Frear, *Chemistry of the Pesticides*, 3rd ed. (1955); R. L. Metcalf, *Organic Insecticides: Their Chemistry and Mode of Action* (1955); G. H. Ahlgren, G. C. Klingman, and D. E. Wolf, *Principles of Weed Control* (1952). Bulletins on spraying and dusting practices are available from most state agricultural experiment stations. (W. E. Ls.)

**SPREE**, a river of Germany about 247 mi. (398 km.) long, of which about 90 mi. are navigable, with a drainage area of 3,900 sq.mi. (10,100 sq.km.). The river rises in the mountains of upper Lusatia, near the Czechoslovak frontier, and flows north past Bautzen, Spremberg, and Cottbus, dividing between the first two towns for a time into two arms. Below Cottbus the river splits into a network of channels, forming the marshy region known as the Spreewald as far as Lübben, then passes Fürstenwalde and Köpenick, and winds through Berlin in several branches to join the Havel (a tributary of the Elbe) at Spandau. The Spree is connected with neighbouring rivers by canals. The chief of these is the Oder-Spree Canal, which runs southeast from Berlin.

The Spreewald is a dominantly forested area, about 37 mi. (60 km.) long and up to 5 mi. (7 km.) wide; forest clearance and drainage of the bogs were encouraged by Frederick II the Great. Much of the land is now cultivated (market gardening). Many towns and villages are accessible only by boat in summer and skis in winter. This is an area of survival of Slav (Wendish) dialects, customs, and folk dress. See LUSATIA. (R. E. Dr.)

**SPRING** is, in almost all cases, the natural overflow or point of escape from some underground reservoir of water. Its classification may be either according to the geological conditions governing the point of location or according to the chemical com-

position of its waters. When considerable chemical impurity is present, it is usually termed a "mineral spring."

The rocks that constitute the crust of the earth are either permeable or impermeable to water. During most seasons of the year, in temperate climates, a certain amount of rainfall soaks into any crust formed of permeable strata; the part absorbed may be the complete rainfall during winter months, when the air is saturated with moisture, or may fall to near zero during a dry summer, when all the rainfall is returned to the air as evaporation from the surface. That portion of the rainfall that soaks down below the level of plant roots goes to replenish the underground reservoir. The shape of the reservoir varies indefinitely, according to the geological structure of the area; but it is only the shape of its water surface that concerns springs. This surface, known as the water table, divides the fully saturated rocks from those that only hold moisture in their minute pores.

In an area of completely permeable rocks the springs issue at or near the valley bottoms; when, however, the district is made of alternating permeable and impermeable beds, each impermeable bed holds up water on its surface. If the strata are horizontal, small springs may be found all round the outcrops; but if they are tilted or folded, the flow of the underground water will be toward the lowest point on the base of the permeable water-bearing bed. At this point the main spring for that local reservoir will be located.

In strata that are, in the main, impermeable but somewhat brittle, the presence of joints and cracks is of prime importance in determining the direction and amount of flow in the underground waters. In jointed rocks the rainwater may sink to great depths down one set of joints and rise again along a second, issuing at the surface as a warm or thermal spring; this is the probable cause of the hot springs at Bath. When a permeable bed and an impermeable one are brought into juxtaposition through faulting, the flow of water in the permeable one is checked; but since faulting frequently shatters the rock, it affords a plane of weakness along which the water will tend to flow. If the water is flowing under pressure due to an overlying impermeable cover, it may reach the surface as an artesian spring. The water of artesian springs sometimes carries small particles of solid matter in suspension, as well as salts in solution. The solid particles are dropped at the point of exit of the spring and may be cemented by the salts deposited from solution. When this takes place, a mound is built up, from the summit of which the spring issues. Hence the "mound springs," such as are seen at their best in the great artesian basin of Australia.

Some of the largest springs issue from thick beds of massive limestone. This type of rock is usually well jointed, and, being soluble in rainwater, the joints and marked bedding planes become enlarged by solution, and the whole of the rainfall is absorbed in the mass of the rock and flows underground to issue as large springs. Frequently these springs yield a somewhat hard water of otherwise great purity.

**Mineral Springs.**—All springs containing noticeable quantities of salts in solution, other than the carbonate and sulfate of lime, are known by this name. The commonest minerals found are common salt, giving rise to "bitter springs"; and iron, sulfur, magnesia, etc., giving medicinal waters.

**Thermal Springs.**—The springs coming under this heading are derived from two sources. Firstly, meteoric waters (those derived from the atmosphere of the earth), which have penetrated down to considerable depths and rise again along well-defined fissures issuing as springs at the surface but with the temperature of the rocks from which they have come; and, secondly, volcanic waters, either in the form of geysers or hot springs (*see* VOLCANO); in these the water may be either meteoric or in part, at any rate, juvenile (water issuing at the surface for the first time). Most of these waters contain mineral substance in solution, which is deposited on cooling and forms basins and terraces of sinter, such as the famous pink and white terraces of New Zealand.

(W. B. R. K.)

**SPRINGFIELD**, the capital city of Illinois, U.S., and the seat of Sangamon county near the Sangamon river, 99 mi. N.E.

of St. Louis, Mo., and 185 mi. S.W. of Chicago, Ill. In the winter of 1818–19 several adventurous settlers located in the area, although John Kelly is acknowledged to be the first to build a cabin (at the northwest corner of Second and Jefferson streets) where the city now stands. Others, generally from North Carolina, Virginia and Kentucky, built near this cabin. In 1821 Sangamon county was created and the little settlement was named temporary county seat; the following year a post office was put into operation. The village was confirmed as county seat in 1825 and incorporated in 1832, and in 1837, with a population of less than 3,000, it was selected as the capital of Illinois.

Those most responsible for the legislative transfer of the capital from Vandalia to Springfield were the Sangamon county representatives, the "long nine" (so called because their aggregate height was 54 ft.). Their leader was young Abraham Lincoln, who came to Springfield from the rude village of New Salem (25 mi. N.W. of Springfield) on April 15, 1837, and lived there until he left for Washington, D.C., on Feb. 11, 1861, to be inaugurated as president of the U.S. Lincoln and the city matured together and the many places identified with his life attract hundreds of thousands of tourists annually.

The old state capitol building (begun in 1837, completed in 1853), rebuilt in the 1960s as a state shrine, is located in the centre of the business district. There Lincoln served his last term in the legislature, 1840–41, practised before the state supreme court, delivered several of his most notable speeches, including the "House Divided" address, and maintained an office as president elect; and it was there that his body lay in state (May 4, 1865). An unpretentious house at Eighth and Jackson streets, maintained by the state of Illinois as a memorial, is the only home owned by Lincoln. He purchased it for \$1,500 in 1844 and in it three of his children were born; the house has been restored and many of the original furnishings are on display.

One and a half miles northwest of the business district is the Lincoln tomb and memorial in Oak Ridge cemetery. The marble burial chamber on the ground floor holds the bodies of Lincoln, his wife Mary and three of their children, Edward Baker, William Wallace and Thomas ("Tad"); their other child, Robert Todd, is buried in Arlington National cemetery. The memorial is 117 ft. tall and is surmounted by a granite shaft. The state of Illinois owns and maintains the structure. The present tomb and memorial is the third erected on this site. The last reconstruction was completed in 1931 with a new interior but without change to the exterior. The First Presbyterian church displays the original pew rented by the Lincoln family. The Wabash railroad passenger station, although converted to freight use, is still standing; there Lincoln delivered his celebrated Farewell Address. The locations of Lincoln's three law offices, the Globe tavern, the place where the First Inaugural was written, and other spots of Lincoln interest are marked with bronze plaques.

In the centre and towering over the Illinois state buildings is the statehouse, the fifth capitol building owned by the state. Begun in 1868 and finished in 1888 at a cost of \$4,500,000, this massive limestone structure is in the form of a Latin cross and measures 361 ft. in height (to the top of the flagpole, 405 ft.). Extensive interior renovation was done in 1958. The Centennial building, southeast of the statehouse, erected 1918–23 at a cost of \$3,000,000, commemorates the 100th anniversary of Illinois statehood; it houses the state historical library, museum, hall of flags, state library and other state offices. In the historical library is a famous collection of Lincoln letters, documents and memorabilia as well as extensive collections concerning the history of Illinois. Immediately west is the state archives building, the third of its type in the U.S.; completed in 1938 at a cost of \$820,000, its unique construction provides superior protection to the official, noncurrent records of the state. Immediately northwest of the archives is the state office building, first occupied in 1955 (cost, \$11,500,000); within this modern structure is a post office, a cafeteria and the offices of more than 20 state departments. North of the capitol is the state armoury and office building; completed in 1937 and costing more than \$1,000,000, it replaced an armoury destroyed by fire in 1934. The supreme court build-

ing, adjacent to the Centennial building, is occupied by the two highest Illinois courts and by the attorney general. The governor's mansion, a short distance away, was first occupied by Gov. Joel A. Matteson in 1855 and has since been the residence of Illinois governors.

Springfield is a large wholesale and retail centre for a rich agricultural area; the once significant soft coal industry is no longer important to the city's economy. Principal industrial products include electric meters and electronic equipment, tractors, heavy-duty boilers, castings, automotive equipment, miners' lamps, mattresses and shoes, boxes, paints, livestock feeds, soybean oil and meal, and flour and cereal products. City parks total about 1,000 ac. Around Lake Springfield, completed in 1935 to provide water, the city has developed residential and recreational areas.

Pop. (1960) city, 83,271; standard metropolitan statistical area (Sangamon county), 146,539. For comparative population figures see table in ILLINOIS: *Population*. (C. C. W.)

**SPRINGFIELD**, a city of Massachusetts, U.S., on the east bank of the Connecticut river is the seat of Hampden county and a central city of the Springfield-Chicopee-Holyoke standard metropolitan statistical area (SMSA). This area comprises four cities (Chicopee, Holyoke, Springfield, Westfield) and ten towns (Agawam, East Longmeadow, Hampden, Longmeadow, Ludlow, Monson, Palmer, Southwick, West Springfield, Wilbraham) in Hampden county; one city (Northampton) and four towns (Easthampton, Granby, Hadley, South Hadley) in Hampshire county; one town (Warren) in Worcester county; and one town (Somers) in Tolland county, Conn. Most of these municipalities were part of Springfield when it was incorporated in 1641. Pop. (1960) Springfield, 174,463; Springfield-Chicopee-Holyoke SMSA, 493,999. (For comparative population figures see table in MASSACHUSETTS: *Population*.)

Springfield, the financial, commercial, and industrial centre of the area, is the third largest city in Massachusetts. Its population has grown at a fairly consistent pace, the 1960 census figure being two and a half times that of 1900. Its area provided ample room for internal population growth so that the surrounding communities did not start growing at a more rapid pace than the core city until the middle of the 20th century.

The metropolitan area covers much of the Connecticut valley lowland that stretches about 30 mi. N. from the Connecticut border and from the Berkshire foothills in Westfield to the eastern uplands in Wilbraham. The Westfield and the Chicopee rivers, two tributaries of the Connecticut, cut the area east and west. The land is fairly flat, although it is broken by a series of traprock ridges which add interest to the terrain.

The region was settled in 1635 by William Pynchon, one of the original patentees of the Massachusetts Bay Colony, and a group from Roxbury, Mass. The patentees moved from what is now Agawam to the east side of the Connecticut river the following year for greater safety from the Indians and they called the community Springfield after Pynchon's home in England. Their leader's autocratic rule ended in 1652 when Pynchon returned to England as a result of the furor caused by his book attacking the Calvinist doctrine of atonement. The settlement was an agricultural and trading community at first; its industrialization was hastened by the building of an arsenal which received congressional endorsement in 1777; by the development of water power, especially in Chicopee and Holyoke, in the early 19th century; and by the arrival of the railroad in 1835.

Machinery, electrical equipment and printed goods are the most important products of the highly diversified economy of Springfield. The U.S. arsenal and an armoury, established in 1794, have long been important. More than 800,000 of the famous Springfield muskets were made there during the Civil War. It later became the home of the famous Springfield rifle and the Garand rifle and a principal manufactory of small arms for the U.S. army. The Smith and Wesson revolver factory is located there. G. & C. Merriam company, publishers of Merriam-Webster dictionaries since 1843, has its headquarters in Springfield.

Springfield was incorporated as a city in 1852. Long unique in

Massachusetts for its partisan municipal elections and bicameral city council, the city voted in 1959 to change to a strong-mayor, unicameral-council government with nonpartisan elections. Evidence of city planning and of an active cultural life are seen in the so-called municipal group, consisting of the city hall and the municipal auditorium that houses the city's symphony orchestra, and in a nearby quadrangle made up of art and natural history museums, a planetarium and a library. Springfield College, founded in 1885 by the Young Men's Christian association, and American International college, established in Lowell in 1885 as the French-Protestant college and moved to Springfield in 1888, are the two major institutions of higher private education in the city, which has long had a reputation for its excellent schools. The city's extensive park system consists of 2,000 ac. and includes one of the largest zoos in New England. (GE. G.)

**SPRINGFIELD**, a city of southwestern Missouri, U.S., the county seat of Greene County. Kansas City, 175 mi. NW, is the nearest larger city. Until the end of World War II Springfield was commercially important chiefly as the centre of a fertile agricultural area, as a distribution point for manufactured products and as the seat of the major shops of the St. Louis-San Francisco railroad. Its rapid growth after that time is attributable mainly to the expansion westward of eastern manufacturing firms. Springfield's population in 1960 was 95,865; that of its standard metropolitan statistical area (Greene County) was 126,276. (For comparative population figures see table in MISSOURI: *Population*.)

Springfield was first settled in 1829 by families from Tennessee and Kentucky. The Civil War split friends and families; the merchants and professional men, largely from the southern lowlands, included many slaveowners, while the settlers with rural backgrounds, mainly from the mountain regions, sympathized with the North. Springfield became a strategic point in the war and a battle was fought at Wilson's Creek, 10 mi. from the city. In a federal cemetery Confederate and Union graves lie side by side.

There are three liberal arts colleges in the city. Drury (Congregational) was established in 1873, Southwest Missouri State began as a teachers' college in 1905 and Evangel (Assemblies of God) was established in 1953. In addition, there are two college-level religious-training institutions—Central Bible Institute (Assemblies of God) and Baptist Bible College.

Besides farm products—chiefly meat, livestock, dairy products, small fruits, eggs and poultry—Springfield produces paper cups, machine belts, portable typewriters, flooring, furniture, truck trailers and men's clothing. Institutions include a federal prison hospital and the international headquarters of the Assemblies of God. Springfield is also the seat of a Roman Catholic diocese. Church membership in the city is about 95% Protestant.

Within a 50-mi. radius from Springfield are Ozarks resort areas, with stretches of scenic beauty in between, and the city is a popular stopover for tourists. It is noted for its pleasant tree-lined streets and attractive residential areas. Springfield adopted the council-manager form of government in 1953. (E. R. St.)

**SPRINGFIELD**, a city of Ohio, U.S., 45 mi. W of Columbus and 82 mi. N of Cincinnati; the county seat of Clark county. Scattered settlements had been made in this region before James Demint built his log cabin on Lagonda (now Buck) creek in 1799. Two years later a townsit was surveyed on the river bottomlands opposite; the settlement is said to have been named Springfield because of spring water coming down the cliffs bordering the valley. The rapid influx of settlers led the Ohio legislature in 1818 to establish Clark county with Springfield as the county seat. In 1850 it was made a city, its population at that time being 5,108. The population of Springfield in 1960 was 82,723 and that of its standard metropolitan statistical area (Clark county) was 131,440; for comparative population figures see table in OHIO: *Population*.

The economic life of the residents rests on the processing of the products of the surrounding farms and the output of over 200 manufacturing establishments. A wide variety of industrial products ensures business stability and well-paid labour.

Educational facilities include Wittenberg University, a Lutheran institution chartered in 1845, Roman Catholic and public schools. The Warder Public library serves all of Clark county. Springfield

supports a symphony orchestra. City parks cover over 600 ac. Ten miles west of Springfield lies the Wright-Patterson air force research and development base, a national centre for defense activity. Many Springfield residents find employment there.

(B. H. P.)

**SPRING-RICE, SIR CECIL ARTHUR** (1859–1918), British diplomat, ambassador to the United States from 1913 to 1918, was born in London on Feb. 27, 1859, the second son of the Hon. Charles Spring-Rice. Educated at Eton and Balliol College, Oxford, he entered the foreign office in 1882. He became private secretary to the earl of Granville in 1884 and précis writer to the earl of Rosebery in 1886, in which year he was sent to Washington as third secretary. After progressing through many foreign postings, he was knighted and sent as minister to Persia in 1906. He became minister to Sweden in 1908 and ambassador to the United States in 1913. At Washington, after the outbreak of World War I, he had to conduct the delicate negotiations arising out of the frequent clashes between Britain's war operations and the neutral rights of the United States. His knowledge of that country and sympathy for its ideals, and his gifts of tact and conciliation, made him an ideal representative at a crucial time. His labours took a heavy toll of his strength, and after retiring in January 1918, he died at Ottawa, Ont., on Feb. 14, 1918.

See S. Gwynn (ed.), *The Letters and Friendships of Sir Cecil Spring-Rice*, 2 vol. (1929).

(H. G. N.)

**SPRINGS**, a town of the Transvaal, in South Africa, lies 28 mi. E of Johannesburg. Pop. (1960) 137,253, of whom 36,935 were European, 97,406 Bantu, 1,375 Asian, and 1,537 Coloured. The town has been a municipality since 1904 and the seat of a magistracy since 1909. Its life began with the opening of the first coal mine in 1885. In 1908 the mining of gold started at Geduld mine, and the closing in 1913 of the last colliery left gold mining as the sole industry. During the next 25 years Springs became the most highly concentrated gold-field in the world. Two of the mines also yield uranium, and an extraction plant was officially opened in 1953. Secondary industry has gradually been attracted to the town, and factories include those for the making of paper, glass, machine tools, alloy steels, electrical goods, and bicycles. Educational training facilities include a branch of the Witwatersrand Technical College and a government miners' training school. Springs has rail and road communication with other important centres, including Durban (410 mi.) and Lourenço Marques (393 mi.); Johannesburg is linked by electric railway. Jan Smuts Airport, the principal air terminal of the country, is 18 mi. from Springs by road.

**SPRINGTAIL**, any one of a group of small (minute to about  $\frac{1}{2}$  in.), primitive, wingless insects of uncertain origin and relationship, so called because many species possess appendages under the abdomen which can be forced down and back, catapulting the insects into the air. They are widely distributed, ranging from the Antarctic to the Arctic, and are abundant, though often unobserved, in moist plant debris. Certain springtails known as snow fleas are active at near-freezing temperatures and may appear in large numbers on snow surfaces. Although they usually feed on decaying vegetable material or fungi, they occasionally attack living plants, and some species are predatory or feed on animal material. Young, which hatch from spherical eggs, closely resemble the adults.

The lucerne flea causes crop injury in Australia and the garden springtail attacks many cultivated plants in North America. Occasionally springtails are pests of mushrooms, and two species are nuisances in houses. Springtails belong to the order Collembola, which is separated into two suborders, one in which the body is elongate with discrete abdominal segments, the other in which the body is oval or globular, most of the abdominal segments having united with the thorax. See also INSECT.

(H. B. M.)

**SPRUCE**, an important genus (*Picea*) of evergreen trees in the pine family (Pinaceae), including about 40 species native to the temperate and cold regions of the northern hemisphere. They are pyramidal trees with whorled branches; thin, scaly bark; linear, spirally arranged leaves, each jointed near the stem on a separate woody base; and ovoid to cylindrical pendent cones. The spruces

are distinguished from the pines by solitary instead of fascicled leaves, which leave peg-like projections on the twig when they fall, and from firs in having pendent, persistent-scaled, instead of upright, deciduous-scaled cones. Spruce trees are subject to severe damage from pests and fire.

Seven species of spruce occur in the United States and Canada, 1 in Mexico, 2 in Europe, and 29 in Asia. North American spruces have light, soft, compact, straight-grained wood that is strong, easy to work, and low in resin content. The wood is resonant and used extensively for sounding boards in pianos and the bodies of violins. It is used also for construction, boats, oars, boxes, food containers, barrels and casks, and many other products requiring light, strong, elastic wood. Its chief use has been for pulpwood, 3,000,000,000 to 4,000,000,000 bd.ft. of spruce timber going into pulpwood annually, with cutting exceeding natural replacement.

The red spruce (*P. rubens*) is important from Nova Scotia to New York and through the Appalachians to Georgia. Most trees attain a height of 60 to 100 ft. and diameters to 24 in., but specimens 4 ft. in diameter and 120 ft. tall have occurred. The boles are slenderly cylindrical and rise from shallow, widely spreading root systems. Vigorous trees begin to produce seed when 30 to 40 years old, mature in about 100 years, and may live 300 to 400 years.

Black spruce (*P. mariana*) and white spruce (*P. glauca*) have almost the same range—from Labrador to New York and the Great Lakes, thence across Canada into Alaska, where they reach the arctic tree line. Both are used for pulp; white spruce produces good lumber, and black spruce is the source of spruce gum. White spruce sometimes reaches a height of 120 ft., but usually is 60 to 70 ft. tall and 18 to 24 in. in diameter. It forms extensive pure stands or is mixed with other conifers, aspen, balsam poplar, and birch. The cones of black spruce are purplish, those of white spruce brownish, just prior to maturity.

In the west, Engelmann spruce (*P. engelmannii*), the most important spruce lumber tree, attains a diameter of 18 to 30 in. (exceptionally to 6 ft.) and a height of 100 to 165 ft. It grows best on loamy soils with high moisture content, but matures slowly. Trees 400 to 600 years old have been reported. It produces large crops of seeds at three- to six-year intervals, and the small seeds (average, 135,000 per pound) have a high germination rate, often to 97%. Reproduction by seed is excellent in both humus and mineral soil. Layering sometimes occurs, but trees from such origins usually are stunted. Engelmann spruce ranges from 1,500 to 12,000 ft. in altitude, from British Columbia and western Alberta to Montana, northeastern California, and New Mexico. Living timber of Engelmann spruce has been estimated at 63,000,000,000 bd.ft., with half of this reserve in British Columbia.

The blue, or Colorado, spruce (*P. pungens*) ranges from Yellowstone National Park to Idaho, central Utah, and southern Arizona, at altitudes slightly below the Engelmann spruce belt. It is smaller than the latter tree and, although of some importance for lumber, the trees grow scattered or in small patches so logging is expensive. Because of the bluish caste of the foliage and its symmetrical growth in open situations it is used extensively as an ornamental. Its deep root system makes it remarkably windfirm and resistant to drought.

The above species have four-angled leaves, but weeping spruce (*P. breweriana*) and Sitka spruce (*P. sitchensis*) have flattened leaves. The weeping spruce, confined to the mountains of northwestern California and adjacent Oregon, has slender, pendent twigs and drooping branches that often reach the ground. The tree has little commercial value. Sitka spruce ranges along the coast from the base of the Alaska peninsula to California and to about 50 mi. inland. It is the largest of the new world representatives, trees 4 ft. in diameter and 200 ft. tall being common; a specimen 16 ft. in diameter and 300 ft. tall has been reported. Most mature trees scale 6,000 to 8,000 bd.ft., but exceptionally large ones have run to 40,000 bd.ft. of usable timber. Production of Sitka spruce lumber in Washington and Oregon alone amounted to 106,580,000 bd.ft. in 1948 but since that time has steadily declined.

The most important European spruce is the Norway spruce (*P. abies* or *P. excelsa*), native to northern Europe and used ex-

tensively in reforestation there and in North America. It approaches Sitka spruce in size, some trees attaining 170 ft. in height and a diameter of 5 to 6 ft. The branches have a tendency to droop, the lower ones often touching the ground. Its six- to seven-inch long cones are heavy seed producers and are confined to the tips of the upper branches. The species ranges from Norway to the Lena River in Russia and from latitude 68° N to the Pyrenees, the Swiss Alps, and the Altai Mountains. It furnishes lumber, poles, mining timbers, pulpwood, and limited quantities of material for making stringed instruments. It is planted widely as an ornamental. It stands the smoke of cities better than most members of the family, although aged trees sometimes are disfigured by blight and insect attack.

ROCHE  
NORWAY SPRUCE (PICEA ABIES)  
BEARING CONES

Among the Old World spruces used ornamentally are the Serbian (*P. omorika*); Oriental (*P. orientalis*) of Asia Minor; Himalayan spruce (*P. smithiana*); Alcock spruce (*P. bicolor*); and the tiger's-tail spruce (*P. polita*), the last two being native to Japan.

Dallimore and A. Jackson, *A Handbook of Coniferae* (1948); W. Harlow and E. Harrar, *Textbook of Dendrology* (1958). (I. L. W.)

**SPRUE (PSILOSIOS)** is a deficiency disease characterized by voluminous frothy stools, gastrointestinal distention and discomfort, sore tongue (glossitis), weakness, marked loss of weight, and anemia. It occurs primarily among Caucasians residing in hot climates. Infrequently it develops in natives of the tropics and in Caucasians in cooler climates. Sprue is characteristically a disease of middle life and is more common in women than in men. It much resembles celiac disease (idiopathic steatorrhea), which occurs chiefly in children.

Sprue is associated with nutritional deficiency, resulting from (1) inadequate supply of animal proteins, whole cereals, and fresh fruits or vegetables containing certain vitamins, iron, and calcium salts, together with excessive intake of carbohydrates; (2) inability of the intestine to absorb adequate amounts of essential food elements; (3) inability of the stomach to secrete essential components of gastric juice; or (4) a combination of these factors. Previous intestinal disease or some other debilitating condition may be a precipitating or contributory cause.

Sprue is typically insidious in its onset. The patient develops an inflamed, denuded, extremely sore tongue and copious, frothy, watery stools, with associated intestinal tenderness and at times colicky pains. Examination shows that the stools contain inadequately saponified fats. The food deficiencies produce subtotal atrophy of the intestinal villi, which, in turn, is responsible for inadequate fat digestion and absorption. The patient may also have low blood pressure, and at times subnormal temperature, moderate to advanced emaciation, early loss of weight, increasing weakness, and macrocytic hyperchromic anemia; during remissions these symptoms tend to improve but return with each relapse. The clinical findings as a group distinguish sprue from the usual type of pernicious anemia, pellagra, chronic colitis, diabetes, tuberculosis, and cancer, although any one of these diseases may complicate sprue.

Prevention of sprue consists primarily in observance of an adequate, balanced diet and early correction of intestinal disorders. Treatment is based on administration of folic acid together with a low-fat, gluten-free diet rich in vitamins and protein. Corticosteroid therapy often is dramatically effective in relapsed cases.

**SPURGEON, CHARLES HADDON** (1834-1892), English Baptist minister, one of the most popular and prolific preachers in an age of great preaching, was born at Kelvedon, Essex, on June 19, 1834. His father and grandfather were Congregational ministers, but in 1850 he joined the Baptist Church and in the same year preached his first sermon. In 1852 he became minister at Waterbeach, Cambridgeshire, and in 1854 minister of New Park Street Chapel, Southwark, London. Within a year this was too small to hold the congregations who flocked to hear him; a larger new building also proved inadequate, and while the huge Metropolitan Tabernacle, Newington, was being built, Spurgeon preached to crowds of over 10,000 at the Surrey Gardens Music Hall. The Tabernacle (which held 6,000) was opened in 1861, and from then until his death (at Menton on Jan. 31, 1892) Spurgeon continued to attract vast congregations, also publishing sermons that, collected, fill more than 50 volumes. He edited a monthly magazine, founded a college for ministers (1856) and an orphanage (1867), and wrote a number of books, the best known being *John Ploughman's Talks; or, Plain Advice for Plain People* (1869). His sermons were widely translated, and their sales were astronomical.

Spurgeon was a fundamentalist, and in 1887 distrust of modern biblical criticism led him to leave the Baptist Union. His theme was personal salvation, and he combined sincerity with natural gestures, easy delivery, and skilful choice of illustration, often humorous and always homely. See also **PREACHING**.

**BIBLIOGRAPHY.**—*Autobiography*, compiled from his diary, sermons, records, and letters, 4 vol. (1897-1900; rev. ed. of vol. i and ii as *The Early Years*, 1962); *Letters* (1923); see also lives by R. Shindler (1892); W. Y. Fullerton (1920); and J. C. Carlile (1933); and W. M. Smith (ed.), *The Treasury of C. H. Spurgeon* (1956).

**SPURN HEAD**, foreland of the North Sea coast of Yorkshire, Eng., projecting across the mouth of the Humber. From Kilnsea it is 4 mi. long but seldom exceeds 300 yd. wide. Formed of sand and shingle from the rapidly denuding Holderness coast to the north, it is only a few feet above sea level.

**SPY:** see **ESPIONAGE; INTELLIGENCE, MILITARY AND POLITICAL.**

**SPYRI, JOHANNA** (née **HEUSSER**) (1827-1901), Swiss writer whose story for children, *Heidi*, is loved all over the world. Her psychological insight into the child mind, her humour, and her ability to enter into childish joys and sorrows give her books their attraction and their lasting value. She was born in Hirzel on Lake Zürich, June 12, 1827; her father was a doctor and her mother a poet. After her marriage in 1852 to Bernhard Spyri, a lawyer engaged in editorial work, she moved to Zürich. Her first book, *Ein Blatt auf Vronys Grab* (1870), was followed by many others. The best known, *Heidi* (2 vol., 1880-81), has been widely translated. Others include *Heimatlos* (1881) and *Grilli* (1882). Johanna Spyri died at Zürich, July 7, 1901. Her love of homeland, feeling for nature, unobtrusive piety, and cheerful wisdom gave both her work and her life their unique quality.

See M. Paur-Ulrich, *Johanna Spyri, ein Lebensbild*, 2nd ed. (1940) (M. P.-U.)

**SQUALL AND SQUALL LINE.** A squall is a strong wind that sets in suddenly, lasts for several minutes then dies away somewhat less suddenly. Any squall includes a succession of gusts, or irregular fluctuations of wind speed at intervals of a few seconds to a minute; an individual gust may be half again as strong as the average squall wind speed.

Wind speeds in squalls commonly reach 30 to 60 m.p.h. (50-100 km.p.h.), and gusts of 80 to 100 m.p.h. (130-160 km.p.h.) or more sometimes occur, although gusts of this strength are rare in most localities. Usually, squalls are straightaway winds, although some types of rotary winds are called squalls (e.g., "typhoon squall," a form of waterspout several hundred yards in diameter).

It is common practice to name a squall after the weather phenomenon which accompanies it: rain, snow, hail, thunder, etc.

The most spectacular common type is the thundersquall. As a thunderstorm approaches, the wind often dies down, then blows gently toward the storm; finally, as the rain is almost at hand, a violent wind abruptly sets in, blowing outward from the storm and usually lasting for only a short time. (See also THUNDERSTORM.)

A squall of this kind is caused by the spreading out of cold air formed in the rain area of the thunderstorm. A thunderstorm, as a whole, is warmer than the surrounding air at a given level. In the heavy rain region, however, a certain amount of relatively dry air, drawn into the thundercloud from the outside, causes partial evaporation of the rain. This evaporation cools the air, and a cold downdraft forms because the air is then more dense than the surroundings, and sinks in the same way as a heavy liquid will sink when poured into a lighter one. As the downdraft approaches the earth's surface, it is forced to spread out horizontally; the squall occurs near the edge and for a short distance within the boundary of the spreading cold air. If the air below a thundercloud is very dry, all rain may evaporate before reaching the ground, and the squall may be dry, often with dust or sand being picked up from the surface. This is a common cause of desert sandstorms.

Local rain squalls of the same nature are very common in the oceanic doldrums, and several may be visible simultaneously from a ship. The wind squalls are often evident from whitecaps traveling over the sea surface.

A different type of squall occurs with the drainage of cold air down steep slopes. Such squalls derive their force from gravity, and depend on the descending air being colder and thus more dense than the air it replaces. The outstanding example of this type of wind is the bora, an extraordinarily fierce wind (intermittent squalls of 100 to 130 m.p.h.) observed during the winter when cold air originating in Russia spills over the mountains of Yugoslavia to the relatively warm coast of the Adriatic sea. Squally fall winds of the same nature are common on mountainous coasts in high latitudes, where cold air from glaciated highlands spills down fiords (Norway, Greenland) or deep valleys (e.g., "williwaws" of Alaska). The force of the wind is increased where the air is funneled between narrow valley walls.

(See also WIND.)

Squalls of a less local character occur with the passage of cold fronts (see METEOROLOGY), where large masses of cold air replace warm air. Although the squall is likely to be most pronounced just when the front passes, high winds with gusts are likely to be sustained for several hours. Special names for this type of wind include "norther" (Great Plains, North America); "pampero" (Argentina, Uruguay); and "southerly burster" (Australia).

**Squall Line.**—A squall line (sometimes, line squall), as the name suggests, is a line along which a number of places simultaneously experience squalls. At one time, this term was used to designate the cold front of a cyclone (*q.v.*) but in modern usage applies only to a line of squalls associated more or less directly with thunderstorms. Such a squall line may be several hundred miles long, but with gaps. The line is usually irregular, consisting of several large clusters of thunderstorms, in some cases separate, but more generally connected by relatively inactive cloud masses or sheets formed from old, decadent thunderstorms.

The first sign of an approaching squall line may be layer clouds, alto-cumulus and dense cirrus types, blown out ahead of the thunderstorms by the strong winds in high levels. The squall line when near at hand may appear as a solid wall of cumulo-nimbus cloud, with low ragged clouds beneath and sometimes an arch or straight line of low cloud with an apparent rolling motion. Most generally, however, the main solid wall of cloud is obscured from a ground observer by general low cloudiness, and the only clear evidence of a squall line approaching may be the line of heavy rain, dark low ragged clouds and lightning.

Passage of a squall line is marked by a sudden onset of strong gusty winds, with a marked change in wind direction and a rapid drop in temperature (perhaps 10° or 15° in as many minutes), followed by heavy rain, thunder and lightning, and often hail. Rain amounts of one to two inches in an hour, with one-half inch in the first ten minutes, are not unusual. On the average, rain

falls for about 45 minutes, with a gradual decrease in intensity after the first rain burst. Arrival of the squall is also signaled by a sudden increase in barometric pressure, often amounting to one-tenth inch mercury or more, followed after a few minutes by a more gradual fall of pressure; at the same time, the wind gradually returns to what it was before the squall line passed.

Since there are gaps between active thunderstorms in a squall line, a considerable variation in weather conditions is to be expected at different points. Thus a squall line passing two towns, 10 or 20 mi. apart, may cause only weak squall conditions at one and violent winds, heavy rain and hail at the other.

The cumulo-nimbus clouds with squall lines generally extend to heights of five to ten miles, and present a considerable hazard to aircraft because of the strong and turbulent vertical air currents within them. Increasingly accurate weather forecasting, together with pinpointing of the thunderstorms by radar and radio direction-finding (static) devices, however, enable aircraft either to circumnavigate squall lines or to fly through the inactive parts.

A squall line may be found at a cold front, but ordinarily either forms ahead of or moves out ahead of the front under the influence of strong winds in upper levels, so that on the average squall lines are found 50 to 200 mi. ahead of the cold front, on the south-east side of a cyclone. In middle latitudes, squall lines most commonly approach from the west or northwest (at a speed averaging 30–35 m.p.h.), while in low latitudes, for example in west Africa, they commonly approach from the east.

Squall lines are most frequent during the spring months, in localities occupied by moist tropical air masses but near the zone of the polar front which separates the tropical from the cooler air masses of higher latitudes. The greatest number of squall lines is observed in the Great Plains and middle western United States, a region open to frequent incursions of both tropical and polar air masses.

Phenomena of the same type are observed in eastern India-Pakistan ("nor'westers") and west Africa ("tornadoes"; not rotary storms as are American tornadoes), which are not associated with air mass fronts in the same way as in higher latitudes.

Although the strong winds occurring with squall lines are responsible for considerable damage, most of the damage reported is due to hail and rotary tornadoes occurring with the squall lines. Most tornadoes are associated with squall-line type thunderstorms, and as many as 20 to 30 or even more have been reported with a single squall line (e.g., May 2 and 3, 1956, United States). Damage from one squall line may run into millions of dollars.

The cause of the squall winds with a squall line is in general the same as discussed above in connection with thundersqualls. The original formation of squall lines, as of thunderstorms in general, is most favoured when the air is unstable, having a strong decrease of temperature with height (see METEOROLOGY), and also when the air is very humid in the lowest few thousand feet and relatively dry higher up. These conditions are best satisfied in moist tropical air during mid-afternoon when surface temperatures are warmest, and there is a strong preference for squall lines to form at that time.

Once a squall line has formed, usually by some kind of lifting of the air near a cold front which sets off the first thunderstorms, it seems to carry with it its own self-regenerating mechanism. A mass of rain-cooled air beneath the thunderstorms spreads out and lifts the warm moist air ahead of the squall line, forming new thunderstorms which become incorporated into the squall line, and these repeat the same process. In this way, squall-line thunderstorms are able to keep going for many hours even during the night. Six to 12 hours is a common duration, but some squall lines have been observed to continue for as long as 36 hours.

Because it is blown out ahead of the cold front by the strong winds in upper levels, a squall line after 12 or 24 hours may be found several hundred miles away from a cold front near which it started, and a new squall line may have been initiated near the same cold front.

**BIBLIOGRAPHY.**—Interesting examples of squalls are given by Sir William Napier Shaw, *Manual of Meteorology*, vol. ii (see especially pp. 374–380; 429) (1942). Detailed discussions of the mechanism of

thundersquall formation are to be found in *The Thunderstorm*, United States Weather Bureau (1949). For complete discussions of squall lines, see Sverre Petterssen, *Weather Analysis and Forecasting*, 2nd ed., vol. ii (1956), and article by J. R. Fulks, "Instability Lines," in *Compendium of Meteorology*, American Meteorological Society (1951). See also reports of U.S. Weather Bureau National Severe Storms Project. (C. W. N.)

**SQUARCIONE, FRANCESCO** (1397-c. 1468), the founder of Paduan Renaissance painting, was an artist of great historical importance, few of whose works survive. Born in Padua in 1397 and active there after 1423, he was associated in 1434 with Fra Filippo Lippi during the latter's stay in Padua. Neither of the extant panel paintings by Squarcione, an undated Madonna in the Staatliche Museen, Berlin, and a polyptych of 1449-52 in the Museo Civico at Padua, throws much light on the nature of his contribution to the early work of his most distinguished pupil, Mantegna, who was a member of Squarcione's workshop before 1448. The only record of his mature style is contained in a cycle of frescoes of scenes from the life of St. Francis on the exterior of S. Francesco at Padua, probably painted between 1452 and 1466. Such compositions as can be reconstructed confirm the traditional view of Squarcione as one of the channels through which the style of the great Florentine Renaissance painters was diffused in Padua. According to Scardeone (the prime source for knowledge of the painter's work), Squarcione had 137 pupils. Among the artists he taught or influenced were Marco Zoppo, Gregorio Schiavone, Cosimo Tura (q.v.), and Carlo Crivelli (q.v.).

See M. Muraro, "A Cycle of Frescoes by Squarcione in Padua," in *Burlington Magazine*, CI, 1959, pp. 89-96. (J. W. P.-H.)

**SQUARE**, in geometry, is a plane rectilinear figure with four equal sides and four right (90°) angles. Such a figure is a special kind of rectangle (equilateral) and parallelogram (equilateral and equiangular). It has four axes of symmetry, and its two finite diagonals (as in the case of any rectangle) are equal. If the side of a square is  $s$ , the area is  $s^2$ , read as "s squared" and derived from this geometric relation. Hence, the algebraic square is the product arising from multiplying any algebraic expression by itself; e.g.,  $(a + b)^2 = (a + b)(a + b) = a^2 + 2ab + b^2$  (see BINOMIAL THEOREM). Latin writers called the side of a square its *latus* (side), and hence the square root of a number was often called the *latus*.

The word also is applied to instruments used for drawing or testing right angles, as in the T square and the familiar carpenter's square.

See also GEOMETRY: *The Beginnings of Geometry: Greek Geometry*.

**SQUARE DANCE** is the term applied to the most popular and widely known type of American folk dance to distinguish it from those types classified as contra, or longways, and circle dances. Historians trace its origin to both the Kentucky running set of English derivation and to the cotillion, a stately French dance in square formation, popular at the court of Louis XV but supplanted later by the quadrille.

The americanized quadrille or square dance begins and progresses rapidly in beautifully ordered patterns within the framework of a relatively compact square, sets of four couples forming its four sides. To the traditional accompaniment of accordion, banjo, fiddle, and guitar and to prompting, patter, and singing calls, couples perform a variety of steps, all based on a smooth, "shuffling" walk. Formerly danced in five main figures, the contemporary square dance is comprised of three. See also QUADRILLE.

Ryan, *Dances of Our Pioneers* (1939); Curt Sachs, *World History of the Dance* (1937); Lloyd Shaw, *Cowboy Dances* (1939). (A. S. D.)

**SQUASH** is the fruit of *Cucurbita maxima* and certain varieties of *C. pepo* (see also PUMPKIN). Summer squash is a quick-growing, small-fruited, nontrailing or bush type of *C. pepo*. The plants are upright spreading, 1½ to 2½ ft. high, and produce a remarkable diversity of fruit forms, ranging from flattened through oblong to elongate and crooked. Colours range from white

J. HORACE MCFARLAND CO  
A VARIETY OF SUMMER SQUASH  
(CUCURBITA PEPO)

leaves have developed and after danger of frost is past.

Winter varieties of squash, *C. maxima*, are long-vining, generally large-fruited, long-season kinds that can be stored many months if kept dry and well above freezing. The fruit stems are greatly enlarged next to the fruits, and the fruits show a wide range of sizes, shapes, and colours. They are higher in nutritive value than summer squash or so-called pumpkins and are commonly baked or made into pies. They are extensively grown in the United States in home gardens, market gardens, and on a large field scale for canning. Squash is native to the New World, where it was widely cultivated by the Indians long before European settlement. (V. R. B.; X.)

**SQUID**, a ten-armed cephalopod mollusk related to the cuttlefish (q.v.). Squids are both coastal (*Loligo*, *Sepioteuthis*) and oceanic (*Ommastrephes*, *Onychoteuthis*); they may be swift swimmers or part of the drifting life of the sea (*Cranchia*). In size they range from about 1 in. to the giant *Architeuthis*, which attains a length of more than 60 ft., including the tentacles.

The common squid of eastern North America, *Loligo pealei*, and its European counterpart, *L. vulgaris*, have an elongate tubular body, a triangular fin on each side posteriorly, and a short compact head with large covered eyes. Eight of the arms bear two rows of suckers on the inner side, the rims protected by a horny ring bearing small teeth. Two of the arms are developed into longer tentacles, slender with expanded ends that bear four rows of suckers with toothed, horny rings. The body of most squids is strengthened by a feather-shaped, internal shell (the "pen" or gladius) composed of a horny material.

The squids, or teuthoids, are divided into two groups: the Myopsida (*Pickfordioteuthis*, *Loligo*), in which the eye is covered by the outer skin of the head, and the sucker rings are smooth or toothed; and the Oegopsida (*Ommastrephes*, *Illex*), in which the eye is exposed, and the suckers may form long, slender hooks or claws (*Onychoteuthis*, *Abrolia*, *Galiteuthis*). The Myopsida are a small, homogeneous, well-distinguished group, but the Oegopsida are varied in form. C. Chun divided the Oegopsida into the Libera, in which the mantle loosely articulates with the head (*Illex*, *Architeuthis*), and the Consuta, in which the mantle is fused at the neck and on either side of the funnel (*Cranchia*, *Taonius*). The Consuta are highly modified forms, often transparent, and poorly known.

Little is known of the life history of squids. *Loligo* is presumed to live only three or four years. The European *Loligo vulgaris* may lay about 40,000 eggs in large clusters attached to floating weeds or other objects. In the Pacific American squid, *Loligo opalescens*, which attaches its eggs to the bottom, the male dies after mating, and the female dies soon after spawning. In mating, the male passes the sperm containers (spermatophores) to the female, where they become cemented to special pads until spawning, when they rupture, releasing the sperm. Larger squids (*Architeuthis*, *Ommastrephes*) may live considerably longer. In *Loligo* the young appear somewhat similar to the adults at hatching, but in the oceanic squids (*Chiroteuthis*, *Ommastrephes*) the young are very dissimilar and have a planktonic larval stage.

The luminescent squids (*Lycoteuthis*, *Abralia*, *Watasenia*) are spectacular creatures bearing numerous light organs embedded in the surface of the mantle, head, arms, tentacles, on the eyeball, or within the mantle cavity. The light is produced by a luciferin-luciferase reaction, as in the firefly, and the photophore may be equipped with light source, reflector, lens, and colour screens. In *Lycoteuthis diadema*, which bears 22 light organs, there are 10 different types. The exact function of the light organs is unknown, but they may be for recognition and for attracting prey.

Squid eyes, as complex as those of man, have cornea, vitreous fluid, iris diaphragm, lens, and pigment screens. In most of the squids they are set into the sides of the head, but in *Bathothauma* and *Corynomma* they project from the head on long stalks. The eyes of a giant squid may have a diameter of 15 in. In *Histioteuthis* the head is asymmetrical, the left eye being about twice as large as the right.

Squids are numerous in the sea and afford food to a host of animals. The sperm whale feeds almost exclusively upon squid, often eating the giant *Architeuthis*. Many commercial bony fishes include squid as an important part of their diet. Squids are highly prized as food by many peoples; there are extensive fisheries in Spain and Portugal, where they are canned in olive oil for export. In Japan 600,000–700,000 tons are landed annually, most of which are dried. There is an extensive fishery in the United States, where squid are exported or sold as bait. In Newfoundland about 49,000 tons of *Illex* were landed in 1964, mostly for bait in the local cod fishery.

See CEPHALOPODA for features of the class to which squids, cuttlefishes, and octopuses belong. (G. L. V.)

**SQUILL**, a bulbous herb of the genus *Scilla*, belonging to the lily family (Liliaceae); several of its species are grown in gardens for their early spring bloom. Squills have narrow, basal leaves and flower stalks that bear blue, purplish, or white, nodding, bell-shaped blossoms in loose clusters. Especially desirable is the early-blooming, shade-tolerant Siberian squill (*S. siberica*), with intense blue flowers on stalks about 4–6 in. high. The later-blooming English bluebells, or wild hyacinth (*S. nonscripta*), and Spanish bluebells (*S. hispanica*) are about a foot high. Squills look best in mass plantings beneath trees or shrubs or in rock gardens. Bulbs planted at intervals in early autumn, set into the soil three times their own depth and three to four inches apart, will provide a succession of blooms in spring.

"Squill" is also applied to the sea onion (*Urginea maritima*), which in its white-bulbed variety was formerly used in medicine. The fleshy inner scales of its bulbs contain several glycosides that act as heart stimulants, expectorants, and diuretics. A red-bulbed variety constitutes the rat poison, red squill.

**SQUINCH**, in architecture, a general term for several means by which a square or polygonal room has its upper corners filled in to form a support for a dome (*q.v.*): by corbeling out the courses of masonry, each course projecting slightly beyond the one below; by building one or more arches diagonally across the corner; by building in the corner a niche with a half dome at its head; or by filling the corner with a little conical vault which has an arch on its outer diagonal face and its apex in the corner. The arched squinch seems to have been developed almost simultaneously by the Roman builders of the late imperial period and the Sassanians in Persia.

Squinsches are often found both in Romanesque architecture (*q.v.*) and Islamic architecture. In Italy the form is either the conical type as in the church of S. Ambrogio at Milan or as a suc-

cession of arched rings as in the 13th-century central tower of the abbey church at Chiaravalle Milanese. More complex forms with niches and colonnettes are characteristic of the French Romanesque of Auvergne, as in the cathedral of Le Puy en Velay (late 11th and early 12th century); the allied churches of the southwest coast, such as Saint-Hilaire at Poitiers, use conical squinsches of the Italian type. Islamic architecture, borrowing from the Sassanian precedent, makes great use of squinch forms, particularly in the Syrian, Egyptian, and Moorish phases; the stalactite work, which is so marked a feature of later Islamic architecture, is, in essence, merely a decorative development of a combination of niche squinch forms. In Gothic architecture (*q.v.*) squinch arches are frequently used on the insides of square towers to support octagonal spires. See BYZANTINE ARCHITECTURE; ISLAMIC ARCHITECTURE; ARCH AND VAULT.

**SQUINT** (STRABISMUS) is a turning of one eye or the other inward (convergent squint, cross-eyedness); outward (divergent squint, walleyedness); or, more rarely, upward or downward (vertical squint). A squint may always affect the same eye (monocular, unilateral squint) or it may affect one eye, then the other (alternating squint). It may arise at any time of life as a result of paralysis of one or more of the muscles of the eye (paralytic squint). Cross-eyedness, the commonest form of squint, occurring in early childhood or infancy, is generally not of paralytic origin; it tends to be familial, and often results from an undue strain of the focusing mechanism (accommodation) of the eyes required by an optical error (farsightedness). However, a squint may have many other causes, including mechanical ones and faults in the neural mechanisms that control the position of the two eyes relative to each other. It is essential for the normal functioning of the two eyes together that they be properly aligned during the early years of life.

If a squint has established itself, the child will neglect the vision in one eye to avoid the double vision that results from improper alignment of the eyes and will develop other faulty visual habits, all of which may make it extremely difficult or impossible to restore adequate binocular vision in later life. Deep-seated loss of vision may occur in an eye that is allowed to be turned all the time.

Children do not outgrow a squint. To allow normal development of visual function and to prevent loss of vision, it is essential that medical advice be sought as soon as a squint is observed. No child is too young to be examined or to have some form of treatment. Such treatment may be by eyeglasses, patching of one eye, exercises, locally applied drugs or surgery, or by a combination of any of these means. See also EYE, HUMAN: *Diseases of the Eye: Diseases of the Extraocular Muscles, Their Nerves and Their Central Control Apparatus*. (H. M. Bu.)

**SQUIRES, SIR RICHARD ANDERSON** (1880–1940), Liberal prime minister of Newfoundland, was born at Harbour Grace, Nfd., on Jan. 18, 1880. He graduated in law from Dalhousie University, Halifax, N.S., and was a member of the Newfoundland House of Assembly from 1909 to 1913, of the Legislative Council from 1914 to 1919, and of the House of Assembly again from 1919 to 1924 and 1928 to 1932. He was minister of justice and attorney general (1914–17), colonial secretary (1917–18), and prime minister (1919–23, 1928–32). He was knighted in 1921.

From 1908 to 1918 Squires belonged to the People's Party, led by his law partner, Sir Edward Morris, opposing the old Liberal Party until 1917 and then cooperating with it in a war coalition. But when Morris was succeeded as prime minister in 1918 by the Liberal leader William Lloyd, Squires left the coalition, denouncing in particular William Coaker, president of the Fishermen's Protective Union (FPU), who had backed the Liberals since 1913. Yet in 1919, when Sir Michael Cashin reorganized the government in a conservative direction, dropping Coaker, Squires proclaimed himself a Liberal and formed an alliance with the FPU leader that was the key to his future success.

Sir Richard remains the most controversial of Newfoundland's prime ministers. His opportunistic political career, marked by personal abuse of his opponents, extravagance, and corruption,

ROCHE  
SIBERIAN SQUILL (*SCILLA SIBERICA*)

was ended by the depression. On the other hand, he promoted education and industrial development, and the Liberal Party that he refounded in 1919 survived him to become the predominant political force in the province after the union in 1949 with Canada. Squires died at St. John's on March 26, 1940. He was a member of the United Church of Canada. (G. O. R.)

**SQUIRREL**, any rodent of the family Sciuridae, but sometimes restricted to the familiar arboreal species. Squirrels are small or medium-sized mammals with strong hind legs and well-developed tails, which in tree-dwelling forms are long and bushy and serve as balancing organs or, wrapped about them, for warmth and protection. There are four toes on each front foot, five on each hind. Each side of the jaw has four or five cheek teeth above and four below; these teeth are rooted and their crowns have low cusps adapted for crushing food—nuts, seeds, grasses, tubers, roots and fruits. Internal cheek pouches provide space for temporary storage of large amounts of food, which may be carried elsewhere or may be stored in a cache for later use. Most squirrels are active in the daytime, the year round. Flying squirrels, however, are nocturnal. Ground squirrels may hibernate in cold climates.

Squirrels as a group are nearly cosmopolitan, occurring in all major land masses except Australia, the extreme polar regions and such islands as Madagascar, New Zealand, New Guinea, and Hawaii. They are particularly numerous in India and the tropics. More than 40 living genera and countless species are recognized; fossils are known from the Miocene of Europe and North America. Throughout their wide range, squirrels have become modified for life in many different ecological situations; they are good examples of the evolutionary process of adaptive radiation.

Most familiar are the tree squirrels of forested regions. In North America the gray squirrel (*Sciurus carolinensis*) prefers heavily forested lowlands, while the larger fox squirrel (*S. niger*) favours open forests of the uplands; but both species have adapted well to urban habitats and are familiar tamed residents in city parks. Each species stores small amounts of food, chiefly hardwood nuts and seeds, in widely scattered caches. Winter nests are carefully made weather-proof dens in holes of trees or tightly constructed twig and leaf nests high in trees; summer nests are large, flimsily made balls of leaves and twigs. Mating occurs in midwinter, and the young, usually two or three, are born about 45 days later. A second mating takes place in late spring. The smaller red squirrels, or chickarees (*Tamiasciurus*), which occupy a wide variety of woodland habitats but are especially abundant in coniferous forests, store food in one or two large reserves, usually in a damp place, and in numerous smaller units. Usually five or six young are born about 40 days after mating.

The common old world squirrel (*Sciurus vulgaris*) ranges from Norway to Japan, with numerous colour variants in different parts of its range. In Great Britain the common squirrel has been largely replaced by the gray squirrel, which was introduced from North America.

Both albinistic and melanistic individuals are common in American gray squirrels. At least three well-marked colour phases are recognized in the fox squirrels. The complex of Asiatic squirrels is an intriguing zoological puzzle. The sharp division of range between the tassel-eared Kaibab squirrels (*Sciurus kaibabensis*), confined to the Kaibab plateau on the north rim of the Grand Canyon in Arizona, and Abert's squirrel (*S. aberti*), on the south rim, is an interesting ecological problem for the zoogeographer.

The pygmy squirrel (*Myosciurus*) of west Africa and the dwarf squirrel (*Nannosciurus*) of southeastern Asia are the size of a

LEONARD LEE RUE III FROM NATIONAL AUDUBON SOCIETY

THIRTEEN-LINED GROUND SQUIRREL  
(CITELLUS TRIDECIMLINEATUS)

mouse, while the black and yellow giant squirrel (*Ratufa*) of the Malay archipelago reaches the size of a house cat. The striped palm squirrels (*Funambulus*) are the commonest species in India. The oil-palm squirrels (*Protoxerus*) and the isindi (*Heliosciurus*) occur in Africa. These tree squirrels are extremely agile and adept at climbing and leaping; they not only ascend but also descend trees head first with ease. A ground squirrel may be any burrowing member of the Sciuridae, but more commonly the term is restricted to the spermophiles, genus *Citellus*, or *Spermophilus*, rodents characterized by having cheek pouches, short ears, long front claws and generally a short tail. They are omnivorous, feeding upon vegetation, seeds, insects, etc. Although chiefly North American, one, known as the suslik, reaches Eastern Europe and others occur in Asia. The arctic species (*C. parryi*) is about 12 in. long, the tail 5 in.; it is yellowish brown, speckled with gray. Rock squirrels (*C. variegatus* and allies) are about the same size, with a longer tail and larger ears. The mantled ground squirrels (*C. lateralis* and *C. saturatus*) are often confused with chipmunks, having black and white lateral stripes. The thirteen-lined ground squirrel (*C. tridecemlineatus*), often called gopher (the true gopher, however, is of a different family), is pale buff, marked with brownish lines and whitish spots.

Among the other ground-dwelling sciurids are the marmots (including the American woodchuck), chipmunks, and prairie dogs (*q.v.*).

Spiny squirrels, a group of African ground squirrels characterized by spiny fur, belong to the genera *Xerus*, *Euxerus*, *Atlantoxerus*, and *Geosciurus*. Their external ears are small or absent and their claws are long and nearly straight. Typical spiny squirrels live in clefts or holes of rocks or in burrows.

Flying squirrels are found in two very different groups of nocturnal, tree-dwelling rodents, in both of which a parachute-like expansion of the skin of the flanks enables them to take long gliding leaps. They all have large, dark-adapted eyes, and are omnivorous, berries, seeds, nuts and insects being the chief diet.

The first group comprises about 11 genera forming the sciurid subfamily Petauristinae and occurs from Scandinavia to Japan and the Malay region, and in North America from northern Canada to Honduras. The greater number of species occur in the Indian and Malayan regions, where some, *Petaurista* species, reach large size, more than a yard in total length, and may be foxy red, red spotted with white, or black in colour. The gliding membranes of these large species are more extensive than those of smaller forms; a fold connects the hind limbs with the tail. Flying squirrels glide from a position high on one tree to a lower level on another tree or log, sometimes covering 200 ft. or more in a glide. Species of the North American genus *Glaucomys* are smaller buff-coloured sciurids.

The second group, called scaly-tailed "squirrels," is African and consists of certain members of the family Anomaluridae, some of which, however, have no parachute. The flying species differ from those of the last group in that the membrane is supported by a bone at the elbow joint instead of by a cartilage at the wrist. There are two flying genera, *Anomalurus* and *Idiurus*, each containing several species. They are all similar in habits to the previous group and, like them, are very squirrellike in appearance. The term "flying squirrel" is also applied to certain marsupials, but these are more properly called flying phalangers (see PHALANGER; MARSUPIAL).

Squirrels sometimes damage crops and occasionally feed on eggs of desirable birds. Certain species carry diseases transmissible to

JOHN H. GERARD

GRAY SQUIRREL (*SCIURUS CAROLINENSIS*)

man, among them the plague, rabies and tularemia. Larger squirrels are often hunted for their palatable flesh and for their pelts, which are used chiefly for trimming. In American folklore one of the ground squirrels, the ground hog or woodchuck (*q.v.*), is a weather prophet (see GROUND-HOG DAY).

See RODENT; see also references under "Squirrel" in the Index. (R. H. MA.; J. E. HL.; X.)

**SQUIRRELFISH** (SOLDIERFISH), a small (less than a foot long), tropical, marine fish, numerous about coral reefs. Squirrelfishes belong to the family Holocentridae, of the order Beryciformes. They have notably large eyes, a strong backwardly directed spine at the corner of the preopercle (on the lower side of the head), a long spinous dorsal fin contiguous with a shorter one of soft rays behind it, a short anal fin with one of its initial spines notably long and strong, a forked caudal (or tail) fin, and the body covered with firm scales of moderate size. Their colours

BY COURTESY OF MIAMI SEAQUARIUM

SQUIRRELFISH (*HOLOCENTRUS ASCENSIONIS*) COMMON TO THE WEST INDIAN REGION

are bright—red and yellow—and lengthwise stripes on the body predominate. Squirrelfishes with larger mouths (*Flammeo*) are sometimes separated generically from those with smaller mouths (*Holocentrus*). About 12 species of squirrelfishes inhabit the waters of Indonesia; 9, some of which are the same, those of Hawaii; about 7 (of which *Holocentrus ascensionis* is the commonest), the West Indian region. (J. T. N.)

**SRIKAKULAM** (formerly CHICACOLE), a town in Andhra Pradesh, India, and the administrative headquarters of the district of the same name. Pop. (1961) 35,071. The town lies on the left bank of the Languliya River, which is crossed by a bridge at this point, about 35 mi. (56 km.) ENE of Vizianagram and 4 mi. (6 km.) from the sea. It contains an imposing mosque built in 1641. The town was formerly noted for its muslins. Under the Mughal emperors it was the capital of one of the Northern Circars (see CIRCAR), as it was later of a British district.

**SRIKAKULAM DISTRICT** has an area of 3,901 sq.mi. (10,104 sq.km.). Pop. (1961) 2,340,878. It was created in 1960 by the division of Vishakhapatnam District. A notable feature of the district is the Machkund hydroelectric project, completed in 1955. (S. GL.)

**SRINAGAR**, the capital of the Indian state of Jammu and Kashmir, lies on both banks of the Jhelum River at an altitude of 5,250 ft. (1,600 m.), about 400 mi. (640 km.) NNW of Delhi. Pop. (1961) 285,257. The river, which winds its way through the city with an average width of 240 ft. (73 m.), is spanned by nine bridges. One of these, of modern design, leads to the shopping centre and to the busy streets on the outskirts of the town. Srinagar is also traversed by a number of canals. The curious grouping of the houses, no two of which are alike, the irregular embankment of the river, and the mountains in the background form a quaint and picturesque spectacle. The town is well known for its mosques, which include the Jami Masjid, originally built at the beginning of the 15th century and reputedly the largest mosque in Kashmir; the Shah Hamadan, constructed entirely of wood; and the Hazrat-bal, with its relic of the Prophet Mohammed. Other notable features are the museum, the Shankaracharya Hill with the temple of Shiva on the summit, the Hari Parbat Hill, and the Dal Lake with its "floating" gardens, bordered by

the famous Mughal Gardens. Among the industries of Srinagar are carpet and silk mills, silver, leather, and copperware manufacture, and woodcarving. Srinagar is linked by air with Delhi and Amritsar and by air and road with Jammu. The town is the seat of the University of Jammu and Kashmir (1948). (S. GL.)

**SRIRANGAM**, a town in Tiruchchirappalli District, Madras, India, stands on an island formed by the bifurcation of the Cauvery River, about 2 mi. N of Tiruchchirappalli City. Pop. (1961) 41,949. The town is celebrated for its great 17th-century temple dedicated to Vishnu, one of the most sacred shrines of southern India. It is composed of seven rectangular enclosures, one within another, the outermost having a perimeter more than two miles in length. A remarkable feature of the temple is the so-called Hall of a Thousand Pillars with its colonnade of rearing horses. There were earlier temples on the site, and several inscriptions are preserved dating from the 10th to the 11th centuries and also from the 12th century, when the theologian Ramanuja lived at Srirangam. At Jambukesvara, near Srirangam, is an important shrine of Shiva. (F. R. A.)

**SSU-MA CH'EN** (145/135-c. 90 B.C.) is the first major Chinese historian of whom there is any appreciable knowledge, and one of the greatest. His lifework, the *Shih Chi* or *Records of the Historian*, completed around 100 B.C., has been widely read not only in China but in Korea and Japan as well, and has exercised a profound influence upon the literature and historiography of those countries.

Scholars disagree on the date of Ssu-ma Ch'ien's birth, some placing it in 145 B.C., others in 135 B.C.; he appears to have died around 90 B.C. In youth he traveled widely through the Chinese empire, gaining firsthand acquaintance with the geography and historic places. Most of his life was spent at the court of Emperor Wu of the Han dynasty. He inherited the court position of grand historian (sometimes translated as "grand astrologer") from his father, Ssu-ma T'an, whom he credits with the conception of the *Shih Chi*. Late in his life, Ssu-ma Ch'ien was condemned to suffer castration for defending a disgraced general. Though it was customary under such circumstances to commit suicide, he chose to bear the disgrace in order to complete his history.

The *Shih Chi* is a monumental work in 130 chapters covering about 2,000 years of Chinese history from the earliest recorded times to the lifetime of the historian. The existing text is very nearly complete. Divided into five sections, the work begins with 12 chapters of basic annals dealing with the emperors who ruled China. These are followed by ten chronological tables listing in graph form the important events of the past with their dates, and eight treatises on such subjects as music, ritual, astronomy, and economics. Thirty chapters entitled "Hereditary Houses" treat the feudal kingdoms of early China. The work concludes with 70 chapters of biographies or memoirs relating the lives of famous men or describing the peoples of Korea, southeast Asia and central Asia with whom the Chinese had contact. Though histories in simple chronicle form existed earlier, this method of dividing material into annals, biographies, etc., was original with Ssu-ma Ch'ien and, in spite of certain disadvantages, was widely imitated in later Chinese historical works.

Ssu-ma Ch'ien's approach to history was essentially biographical. Throughout his work he was primarily concerned with the lives of the great men of the past and the moral inspiration and guidance they provide. Written in a vivid, concise style and enlivened by dramatic scenes and episodes, his history presents an invaluable picture of life in ancient China and has done much to mold the historical consciousness and literary tastes of generations of Chinese.

See Edouard Chavannes, *Les Mémoires historiques de Se-ma Ts'ien*, 6 vol. (1895-1905); Burton Watson, *Ssu-ma Ch'ien: Grand Historian of China* (1958). (B. D. W.)

**SSU-MA KUANG** (1019-1086), Chinese scholar-statesman, compiler, with chosen associates, of the monumental *Tzu-chih t'ung-chien*, or "Comprehensive Mirror for Aid in Government." As an emulation of the *Ch'un-ch'iu*, or "Spring and Autumn Annals," believed to have been edited by Confucius, it presented the general chronicle of Chinese history from 403 B.C. to A.D. 959, from

the standpoint of Confucian moral principles and their practicalities. Its major attention to political events did not result in neglect of other important subjects, such as rites, music, astronomy, geography, and economy. Nor was the Confucian perspective permitted to interfere with Ssu-ma Kuang's rigorous scientific procedure and critical standards. One major weakness is the work's relative lack of analysis of prevailing patterns and underlying trends. Over the centuries, however, many historians were inspired to develop further this annalistic genre, as well as other related genres, such as narrative summaries. By its high level of research excellence, the work also contributed to the "School of Evidence Investigation," which rose in the 17th and 18th centuries. The great Neo-Confucian philosopher Chu Hsi (q.v.) compiled an outline for it, which, in turn, became most influential in Confucian indoctrination. Even in mainland China today, where Confucianism is under attack, Ssu-ma's scholarship still stands high.

Politically, Ssu-ma Kuang led the faction that opposed the reforms of Wang An-shih (q.v.) in 1069–85. Conservative in his interpretation of the Confucian classics, Ssu-ma argued for the cause of good government through moral leadership rather than assertive measures and through improved functioning of tested institutions rather than drastic changes. Shortly before his death, he became the leading minister to initiate the antireform policy of 1085–93, which, however, did not prove to be particularly successful. Nevertheless, he is still remembered as one of the best in the Confucian image—morally upright, learned in many ways, prominent in government. In modern children's books he still sets an example, in the familiar story of how, as a child, he wisely broke a water tank to save from drowning his playmate who had fallen into it.

**ST. or STE.** Geographic names beginning with the abbreviation "St." or "Ste." are entered under "Saint" (English, French) or "Sainte" (French) for consistency. Local usage frequently determines whether "Saint" or "Sainte" is spelled out in full or abbreviated. "São" is used for Portuguese geographic names, and "San" and "Santa" for Spanish and Italian places.

**STABIAE**, an ancient town of Campania in Italy, destroyed by the eruption of Vesuvius in A.D. 79, on the coast at the eastern end of the Gulf of Naples (modern Castellammare di Stabia). Originally an Oscan settlement, it took part in the Social War (the war of the Italian *socii*, "allies") against Rome in 90 B.C. and was destroyed by Sulla in 89, its territory being given to Nuceria as a reward for loyalty to Rome. It was noted for the medicinal properties of its waters, and the neighbourhood became a popular locality for villas. The elder Pliny perished at Stabiae, near the villa of his friend Pomponianus, in the eruption of 79. Subsequent settlement was of minor importance.

Excavations, begun in the 18th century, were recommenced in 1949. The extent of the pre-Roman town (*oppidum*) has been assessed. The layout of the later town (89 B.C.–A.D. 79), unlike the *insula* (grid) planning of many Roman towns, appears to have been adapted to the needs of a spa. A striking feature of the later excavations has been the wall paintings, which compare very favourably with those of Pompeii and Herculaneum.

**STABILIZATION AGREEMENTS, INTERNATIONAL**, are entered into by countries that are large producers or consumers of commodities that play a major role in international trade. Stabilization agreements are made to deal with difficulties that arise with these commodities such as a persistent imbalance between production and consumption, burdensome stock accumulations, and pronounced fluctuations in prices. After the early 1930s such agreements were concluded for a number of commodities, including wheat, sugar, rubber, tea, timber, tin, coffee,

and olive oil. Customarily such agreements were of five years' duration, although some covered shorter periods.

**The Interwar Period.**—The international commodity agreements introduced in the period between World Wars I and II were essentially of a restrictive type; that is, they represented an attempt on the part of producers, acting during general economic depression, to arrest downward trends in prices by restricting supplies flowing to the world market. This was usually achieved by assigning each participating country a basic quota, subject to periodic adjustment in the light of price trends and the market situation generally. Such agreements depend for their success upon an absence of close substitutes for the commodity concerned and upon participation by all the main producing countries. Some earlier attempts to regulate the market through less comprehensive agreements, such as that for rubber between Malaya and Ceylon (1922–28), failed because higher prices merely stimulated production in and exports by countries outside the agreement. The agreements concluded in the 1930s did, in fact, embrace all the major producing countries and they further extended control over supplies by measures such as the prohibition of the export of planting material from participants to nonparticipants.

It is difficult to reach any general conclusions about the effectiveness of these earlier agreements. The 1933 wheat agreement was undoubtedly a failure, its operative clauses for all practical purposes being abandoned toward the end of the first year of its operation. The scheme of export regulation broke down and difficulties arose over the implied obligations of the four principal exporting countries to reduce acreage. On the other hand, the tea agreements (1933 and 1936 [revised 1938]) and rubber agreements (1934 and 1938) regulated exports in accordance with the agreed quotas and exerted a stabilizing and strengthening influence on prices. In 1937 the League of Nations Committee for the Study of the Problem of Raw Materials reported that the regulation schemes then in operation had, generally speaking, "been an important factor in the improvement in economic conditions experienced in producing countries during the depression as well as in the development of international trade."

**World War II and After.**—With the onset of World War II and the consequent disruption of supplies and higher prices, such agreements became largely redundant. However, certain of them, including those for sugar, tea and rubber, were extended by protocol, shorn of any effective quota provisions, largely to ensure the ready availability of machinery to meet expected postwar needs. In the case of wheat the protocol of 1942, signed by Canada, the United States, Argentina, Australia and the United Kingdom, made definite provision for a postwar international wheat conference and established an International Wheat council to review the situation meanwhile. Exceptionally for coffee, the special conditions brought about by the war, particularly the loss of the important European market, themselves gave rise to the first international coffee agreement (1940). Known as the Inter-American Coffee agreement, this was essentially an export quota agreement, but it constituted the first important international commodity scheme in which a consuming country, the United States, participated and played a dominating role by providing through the quota system an organized outlet for exports from Latin America.

In the early postwar years there was no immediate resort to international commodity agreements. Although a series of wheat conferences was held, introduction of the first postwar agreement for this commodity was delayed until 1949. The International Sugar agreement of 1937 became inoperative in 1944, although the International Sugar council remained in existence, and it was not until 1953 that a new agreement was successfully negotiated. Regulation of the rubber market was not resumed after the war because of the need to rehabilitate the far eastern producing areas and because of the rapid development of the synthetic rubber industry. Tea export quotas remained nominally in force until 1955, but in the later years they were in excess of 100% of the high basic quotas established under the 1936 agreement (revised in 1938) and had no real restrictive effect.

The subject of international commodity agreements was given detailed consideration by the preparatory committee (1946–47)

of the first UN conference on trade and employment and later at the conference itself in Havana (1948). The charter of the proposed International Trade organization, agreed upon at Havana, recognized the importance of international commodity agreements in international trade relations, defining their purpose as follows:

to prevent or moderate pronounced fluctuations in the price of a commodity with a view to achieving a reasonable degree of stability on a basis of such prices as are fair to consumers and to provide a reasonable return to producers, having regard to the desirability of securing long-term equilibrium between the forces of supply and demand; to maintain and develop the natural resources of the world and protect them from unnecessary exhaustion; to provide for the expansion of the production of a primary commodity where this can be accomplished with advantage to consumers and producers, including in appropriate cases the distribution of basic foods at special prices; to assure the equitable distribution of a primary commodity in short supply.

The charter also laid down that, in drawing up agreements, use should be made of certain principles which represented a major departure from those of the prewar era. In particular, it called for detailed preliminary studies by all interested countries of the difficulties affecting the commodity in question and for adequate participation in any agreement by importing as well as exporting countries; both groups were to have an equal voice in decisions on substantive matters. Another requirement was that agreements should provide, where practicable, for measures designed to expand world consumption of the commodities concerned.

Although the proposed International Trade organization did not come into existence, the principles set out in its charter provided the basis for all subsequent negotiations on commodity agreements. Each of the agreements introduced after World War II was negotiated at a conference convened under UN auspices following a preliminary report by the Interim Co-ordinating Committee for International Commodity Arrangements, and often after a great deal of further research in study groups and elsewhere. In fact, an outstanding development in international relationships concerning commodities after the war was the support given to such study groups, often on a continuing basis. Through an interchange of information and by other means short of the negotiation of an international agreement, these groups were often able to exert a considerable stabilizing influence on the market.

**Types of Postwar Agreements.**—In the postwar period, to meet the special situations of individual commodities, three main types of agreements were adopted: export restriction agreements, multilateral contracts and buffer-stock agreements.

**Export Restriction Agreements.**—The first type, adopted for sugar and coffee, conformed most closely to prewar methods, with the important modification that the participants included importing countries, which also assumed rights and obligations. For example, in return for assurances regarding supplies, such countries undertook to import their requirements from participating exporting countries. Price ranges were negotiated for sugar, but not for coffee.

**Multilateral Contracts.**—This type of agreement, adopted for wheat in 1949 and again in 1953 and 1956, was an undertaking on the part of exporting countries to sell to participating importing countries a guaranteed quantity of wheat each year at prices not higher than a specified maximum. Each participating importing country undertook to buy from participating exporting countries on demand a guaranteed quantity at prices not lower than a specified minimum. Under the 1959 and 1962 wheat agreements the concept of guaranteed quantities was abandoned. Importing countries thereafter agreed to import stated percentages of their total commercial imports of wheat from member countries, while the exporting countries collectively agreed to supply all the commercial requirements of the importing countries. These obligations applied only under certain price conditions.

**Buffer-Stock Agreements.**—This kind of agreement was introduced only for tin, although it was considered also for other commodities, including rubber and cotton. The successive international tin agreements (including the last prewar one of 1937) aimed at minimizing price fluctuations by empowering the manager of the buffer stock to buy tin, to the limit of his resources, when market prices fell below a certain minimum and to sell it

when a ceiling was reached. Buying and selling operations were also permissible within the upper and lower limits of the price range in order to prevent steep rises or falls in price. The resources for these operations were provided by producing countries in cash, or in metal to a maximum of 75%. Consuming countries might also make contributions to the buffer stock, though they did not do so.

**A Special Type.**—The international agreements on olive oil (1956 and 1962) represent an approach to a particular commodity situation which is difficult to classify. They were concerned less with the physical regulation of the market than with measures to enhance the competitive position of olive oil in world markets. For example, the Olive Oil council, established under the agreements, encouraged uniformity in member countries' legislation classifying and defining olive oil. It also concluded with the International Bureau for the Protection of Industrial Property a working agreement for protection against unfair competition, such as false declaration of origin or misuse of trade names. One of the council's most important activities was the initiation of extensive publicity campaigns to encourage the consumption of olive oil.

**Summary.**—In all the international commodity agreements concluded in the postwar period member countries looked, in varying degrees, beyond the immediate market situation to the basic problems concerning the commodity in question. For example, the agreements paid some attention to the need to expand consumption. The International Coffee agreement of 1963 was designed primarily to relieve the surplus stock position which had burdened the industry for a number of years; to this end producing countries had undertaken to adjust their production to effective demand at the direction of the International Coffee council. However, progress along these lines tended to be slow, for it impinged upon the basic social and economic policies of the countries concerned.

It was not until 1959 that the scope of international wheat agreements was broadened to enable the International Wheat council to undertake annual reviews of the world wheat situation, and participating countries still reserved for themselves complete liberty of action in the determination and administration of their internal agricultural and price policies. None of the other agreements incorporated provision for a formal or direct system of production quotas in importing and exporting countries, but the view was gaining ground that the onus of correcting structural imbalances in the world market should be shared by buyers and sellers alike.

**STADE**, a town of West Germany in the *Land* (state) of Lower Saxony, Federal Republic of Germany, lies on the Schwinge River, three miles from its confluence with the Elbe below Hamburg. Pop. (1961) 30,542. The old town was destroyed in 1659 and rebuilt by the Swedes. It is still surrounded by its moat and is the modern business centre. The Gothic churches of St. Wilhadi and St. Cosmae have survived, and the half-timbered buildings of the old Swedish military establishment dominate the town. Stade is on the Hamburg-Cuxhaven and Stade-Bremerhaven railway lines and has sea communications. Industries include shipbuilding, oil refining, and the production of salt, rubber, wood,

bricks, textiles, and electrical power. Formerly the leading port of the lower Elbe, Stade gained its civic rights in the 12th century. It was a member of the Hanseatic League. From 1648 to 1712 it was under Swedish rule, then passed to Denmark, and in 1715 to Hanover. (B. F. E. W.)

**STADIUM**, a large construction that combines space for games and seats for spectators, such as those erected for football. The term is the Latin form of a Greek word for a standard of length; a *stade* = 600 Greek (Olympian) feet or about 606 modern feet (185 metres). The course for the footrace at Olympia was exactly a *stade* in length, and the word for measurement became transferred first to the race and then to the place in which it was run. Usually the stadiums were U-shaped, with the curve opposite to the starting point. In some instances, the curve led to a slope on which seats were cut into the land. (For the major Greek stadiums, see *ATHENS: Topography and Antiquities: Roman Period*; *OLYMPIA: The Remains: Stadium*.) The Romans built several types of structures for similar purposes: circuses; amphitheatres, also called arenas; and naumachia (*q.v.*), which could be flooded for naval engagements. The most famous of the Roman amphitheatres was the Colosseum at Rome. (See *AMPHITHEATRE*.)

Sports played a minor role in men's lives for many centuries after the fall of Rome, and it was not until modern times that permanent stadiums were again needed. In the interim, temporary stands were built on occasion, such as those erected from time to time in the Place des Vosges in Paris for jousting.

During the 19th century, systematic physical exercise was revived. This led to organized athletics, which became as popular as in ancient Greece. This revival of interest in athletic games brought about the building of structures adapted to the various sports and providing for many thousands of spectators. The first important stadium of modern times was the reconstruction, in Athens in 1896, of an ancient marble one built about A.D. 143 by Herodes Atticus on the site of a still earlier one. It seated 66,000 persons and was undertaken for the first of the modern series of Olympic Games.

Although a few other stadiums were built before 1900, such as

arenas for bullfighting in Spain and Mexico, the great era of modern stadium-building was the early 20th century. In the United States alone more than 100 large stadiums had been built by 1930, many in the 1920s. Most of these were built for college athletic contests, particularly football.

The Municipal Stadium at Rio de Janeiro, Brazil, has the largest capacity of any football (soccer) stadium in the world; for the final game of the 1950 World Cup soccer matches there, the official crowd figures were given as 199,854. This huge enclosure measures  $\frac{1}{2}$  mi. in circumference. The spectators are separated from the playing field by a concrete moat 9 ft. wide and 9 ft. deep. There are nearly 100 rest rooms, 4 first aid and medical suites, a children's nursery, and a post office and telegraph station within this tremendous establishment. It is surpassed in size only by the Strahov Stadium, completed in Prague in 1934 for Sokol gymnastics displays, where up to 240,000 have been accommodated. Among the largest stadiums in the world is the Los Angeles Coliseum, built in 1923, and enlarged in 1932 to accommodate 105,000 persons. The Philadelphia Municipal Stadium, built in 1926 for the Sesquicentennial Exposition and renamed John F. Kennedy Memorial Stadium in 1964, held 102,000. In Chicago, Soldier Field, opened in 1926, had a seating capacity of more than 102,000. The University of Michigan stadium at Ann Arbor was built in 1927 to seat 79,000 spectators; in 1949 seating capacity was raised to 97,000; and in 1956 to 101,000. Other stadiums with seating capacities of more than 100,000 include Hampden Park, in Glasgow, Scot. (149,500); Wembley, North London, Eng. (126,000); Melbourne Cricket Ground, Melbourne, Austr. (116,000); the Rose Bowl, Pasadena, Calif. (103,000); Tsentralnyi Stadium (Lenin Stadium), Moscow, U.S.S.R. (103,000); and Odsal Stadium, Bradford, Eng. (102,500).

**Olympic Stadiums.**—Nearly every country in which Olympic Games are held erects a great permanent stadium for the event. In most instances, entire new stadiums are built. However, Rome, host city to the 1960 Olympics, reactivated its Olympic Stadium with a seating capacity of 100,000, and Tokyo increased the seating capacity of its National Stadium, site of the Asian Games in 1958, from 55,000 to 85,000. The first stadium of the modern

(Above) Gymnastics display in the 1960s at the Strahov Stadium in Prague, the world's largest stadium; (left) city stadium in Peking, filled with spectators at the 1965 Chinese National Games; (right) mass calisthenics before the Olympic Stadium in Berlin, built in 1936 for the XI Olympiad

(TOP, LEFT) EASTFOTO; (RIGHT) MUSEUM OF MODERN ART FILM LIBRARY

type to provide for the full range of Olympic events was that built in 1908 in London, at Shepherd's Bush, for the IV Olympiad. The stands, part of which were roofed, accommodated 50,000 seats. Other Olympic stadiums of interest include the one built in Stockholm in 1912; the severely simple one of Colombes, near Paris, built in 1927; the handsome brick one built at Amsterdam in 1928; and that built in Berlin in 1936 for the XI Olympiad, the last to be held before World War II broke out in 1939. The Helsinki Stadium, built for the XII Olympiad scheduled for 1940 but cancelled by the outbreak of the war, was the scene of the XV Olympiad (1952). (For sites and years of Olympiads see OLYMPIC GAMES.)

**Plans.**—The shapes of stadiums have varied widely, reflecting the variety of uses for which they were built. Some are rectangular in shape with curved corners, others elliptical or U-shaped. In some, the playing field was beneath the ground level with the spectator stands partly or wholly submerged in the excavation. The Yale Bowl, New Haven, Conn., built in 1914 for football, is a closed ellipse in plan. The Harvard Stadium, Cambridge, Mass., built in 1912, is U-shape, open at one end to permit baseball as well. Those built for Olympic Games have generally been rectangular to enclose a large playing field, and with rounded corners for the track. The horseshoe shape has also been used as at Ohio State University, Columbus, in 1922. The most flexible shape was that providing two parallel stands, opposite each other, with the narrow ends open. Some of this type were built with superimposed tiers of seats, others with crescent-shaped stands (Northwestern University, Evanston, Ill., 1926) so that as many seats as possible were opposite the centre of the field. Other types have been used for special purposes, such as Yankee Stadium, New York City, 1923, built primarily for baseball.

**Structure.**—The building of large stadiums in the early 20th century was facilitated by a new method of construction—reinforced concrete. In the hands of skilful engineers and careful workmen, especially in Europe, magnificent stadiums built in reinforced concrete daringly exploited the potentialities of the material; e.g., those at Lyons, built in 1920 by Tony Garnier; at Florence, the Giovanni Berta Stadium, built in 1933 with fantastic external stair towers; and at Bordeaux, built in 1939, remarkable for a roof of graceful, arched sections.

After World War II, stadiums continued to be built in regions where they had previously been scarce, e.g., in South and Central America, and more daring and dramatic applications of reinforced concrete were a conspicuous development. Outstanding examples included the stadiums at Rio de Janeiro, São Paulo, Mexico City, and Cartagena.

The indoor stadium, unknown to the ancients and made possible by modern building and lighting techniques, could be used both night and day the year around. The first important one was the old Madison Square Garden, built in New York City in 1890, and since replaced. For many years the Chicago Stadium (1928) was the world's largest, with a capacity of 20,000.

The second half of the 20th century marked a new era in stadium construction with the erection of the much larger Astrodome indoor stadium in Houston, Tex. Completely protected from

(Left) The Astrodome, Houston, Tex., the world's first air-conditioned stadium, completed in 1965; (bottom left) Athens Stadium, built for the first modern Olympic Games in 1896; (bottom right) the Marble Stadium, Rome, part of the Foro Italico, a complex of monumental buildings in the classic style, inaugurated in 1932

weather by a plastic-paned dome with a span of 642 ft. (196 m.), and high enough to accommodate baseball, it was the world's first weather-free stadium. It is air-conditioned at 74° F (about 23° C) year-round, controlled by a \$4,500,000 air-conditioning system having a capacity of 6,600 tons. The Astrodome has been compared with the Colosseum in Rome, each in its time and place being something very special; the Colosseum in A.D. 80 and the Astrodome in 1965. The Colosseum is four stories high with marble seats, tier on tier. Seating capacity has been estimated anywhere from 40,000 to 50,000. The Astrodome has three times as much space on the arena floor as the Colosseum, 125,000 sq.ft. (11,613 sq.m.) to 42,580 sq.ft. (3,956 sq.m.) for the Rome stadium. The Astrodome can seat 66,000 spectators in its six tiers. Its overall size is 710 by 710 ft. (216 by 216 m.) and the outside wall is 218 ft. (66 m.) high. Built at a cost of \$31,600,000, it is located on a complex of 260 ac. (105 ha.), has parking space for 30,000 cars, and has a lighting system powerful enough to light a city of 20,000 population.

An added spurt in stadium construction in the U.S. was provided by major league baseball's expansion to become truly a national game. In addition to the Astrodome, new stadiums to house new or transplanted teams were constructed in Los Angeles, San Francisco, and Anaheim (in California), New York, Milwaukee, Washington, D.C., Bloomington, Minn., and Atlanta, Ga.

**STAËL, MADAME DE** (BARONNE DE STAËL-HOLSTEIN; née ANNE LOUISE GERMAINE NECKER) (1766–1817), Franco-Swiss woman of letters, whose brilliant personality epitomizes the European culture of her time. Her writings include novels, plays, moral and political essays, literary criticism, history, autobiographical memoirs, and even a number of poems translated or imitated from the English 18th-century elegiacs, Goethe, and Schiller; but her chief literary importance was as a theorist of Romanticism (*q.v.*).

She was born in Paris on April 22, 1766, of Swiss parents: her father was Jacques Necker (*q.v.*), the Genevan banker who became Louis XVI's finance minister; her mother, Suzanne Curchod,

the daughter of a French Swiss pastor, helped her husband in his career by establishing a brilliant literary and political *salon* in Paris.

The young Germaine Necker early gained a reputation for lively wit, if not for beauty. While still a child, she was to be seen in her mother's *salon*, listening to, and even taking part in, the conversation, with that lively intellectual curiosity that was to remain her most attractive quality. When she was 16, her marriage began to be considered. William Pitt was regarded as a possible husband, but she disliked the idea of living in England. She was married in 1786 to the Swedish ambassador in Paris, Baron Eric de Staël-Holstein. It was a marriage of convenience and ended in 1797 in formal separation.

Before she was 21, she had written a romantic drama, *Sophie ou les sentiments secrets* (written 1786; published 1790), and a tragedy inspired by Nicholas Rowe, *Jane Gray* (written 1787; published 1790). But it was her *Lettres sur les ouvrages et le caractère de J.-J. Rousseau* (1788) that made her known. There is in her thought an unusual and irreconcilable mixture of Rousseau's enthusiasm and Montesquieu's rationalism. Under the influence of her father, an admirer of Montesquieu, she adopted political views based on the English parliamentary monarchy. Favouring the Revolution, she acquired a reputation for Jacobinism. Under the Convention the Girondin faction corresponded best to her ideas.

Protected by her husband's diplomatic status, she was in no danger in Paris until 1793, when she retreated to Coppet, Switz., the family residence near Geneva that she herself made famous as a meeting place for some of the leading intellectuals of Western Europe. Since 1789 she had been the mistress of Louis de Narbonne, one of Louis XVI's last ministers. He took refuge in England in 1792, where she joined him in 1793. She stayed at Juniper Hall, near Mickleham in Surrey, a mansion that had been rented since 1792 by French *émigrés*. There she met Fanny Burney (later Mme d'Arblay); but their friendship was cut short because Mme de Staël's politics and morals were considered undesirable by good society in England.

She returned to France, via Coppet, at the end of the Terror in 1794. A brilliant period of her career started. Her *salon* flourished; and she published several political and literary essays, notably *De l'influence des passions* (1796), one of the important documents of European Romanticism. She began to study the new ideas that were being developed particularly in Germany. She read the elderly Swiss critic K. V. von Bonstetten; the German philologist Humboldt; and, above all, the brothers Schlegel.

But it was Henri Benjamin Constant de Rebecque (*q.v.*), her new lover, who influenced her most directly in favour of German culture. Her fluctuating liaison with Constant started in 1794 and lasted 14 years, although after 1806 her affections found little response. It is alleged that he was the father of Albertine de Staël, born in 1796.

At about the beginning of 1800 the literary and political character of Mme de Staël's thought became defined. Her literary importance emerged in *De la littérature considérée dans ses rapports avec les institutions sociales* (1800). This complex work, though not perfect, is rich in new ideas and new perspectives—new, at least, to France. Later Chateaubriand saw in it a "prospectus of Romanticism." The fundamental theory, which was to be restated and developed in the positivism of Hippolyte Taine (*q.v.*), is that a work must express the moral and historical reality, the *Zeitgeist*, of the nation in which it is conceived. She also maintained that the Nordic and classical ideals were basically opposed,

GIRAUDON  
MME DE STAËL. IN 1810  
Portrait by Jean B. Isabey, now in the Louvre

and supported the Nordic, although her personal taste remained strongly classical. Her two novels, *Delphine* (1802) and *Corinne* (1807), to some extent illustrate her literary theories, the former being strongly sociological in outlook, while the latter shows the clash between Nordic and southern mentalities.

She was also important politically and was regarded by contemporary Europe as the personal enemy of Napoleon. With Constant and his friends she formed the nucleus of a liberal resistance that so embarrassed Napoleon that in 1803 he had her banished to a distance of 40 mi. (64 km.) from Paris. Thenceforward Coppet was her headquarters; and in 1804 she began what she called, in a work published posthumously in 1821, her *Dix Années d'exil*. From December 1803 to April 1804 she made a journey through Germany, culminating in a visit to Weimar, already established as the shrine of Goethe and Schiller. In Berlin she met A. W. Schlegel, who was to become, after 1804, her frequent companion and counselor. Her cicerone in Germany was, however, a young Englishman, Henry Crabb Robinson, who was studying at Jena. The journey was interrupted in 1804 by news of the death of her father, whom she had always greatly admired. This greatly upset her, but in 1805 she set out for Italy, accompanied by Schlegel and Sismondi, the Genevan economist who was her guide. Returning in June 1805, she spent the next seven years of her exile from Paris mostly at Coppet.

While *Corinne* can be considered the result of her Italian journey, the fruits of her visit to Germany are contained in her most important work, *De l'Allemagne* (1810). This is a serious study, in which she made known to her contemporaries the Germany of the *Sturm und Drang* movement; *i.e.*, of the years 1770 to 1780. Its only fault is the distorted picture it gives, ignoring, for example, the violently nationalistic aspect of German Romanticism. Napoleon took it for an anti-French work, and the French edition of 1810 (10,000 copies) was seized and destroyed. It was finally published in England in 1813.

Meanwhile Mme de Staël, persecuted by the police, fled from Napoleon's Europe. Having married, in 1811, a young Swiss officer, "John" Rocca, in May 1812 she went to Austria and, after visiting Russia, Finland, and Sweden, arrived, in June 1813, in England. She was received with enthusiasm, although reproached by such liberals as Byron for being more anti-Napoleonic than liberal, and by the Tories for being too liberal. Her guide in England was Sir James Mackintosh, the Scottish publicist. She collected documents for; but never wrote, a *De l'Angleterre: the material for it can be found in the Considérations sur la Révolution française* (1817), which represents a return to Necker's ideas and holds up the English political system as a model for France.

On the Bourbon restoration in 1814, Mme de Staël returned to Paris but was deeply disillusioned: the fall of Napoleon had been followed by foreign occupation and had in no way reestablished liberty in France. During the Hundred Days she escaped to Coppet and in September 1815 set out again for Italy. In 1816 she returned to spend the summer at Coppet. There she was joined by Byron, who was in flight from England after his unhappy matrimonial experience. A strong friendship developed between the two writers.

Mme de Staël's health was declining. After Byron's departure she went to Paris for the winter. Though poorly received by the returned *émigrés* and suspected by the government, she held her *salon* throughout the winter and part of the spring; but after April she was an invalid. She died in Paris on July 14, 1817.

Mme de Staël's purely literary importance is far exceeded by her importance in the history of ideas. Her novels are mediocre, and her plays unactable; but the value of her critical and historical work is undeniable. Though careless of detail, she had a clear vision of wider issues and of the achievements of civilization. Her involvement in, and understanding of, the events and tendencies of her time gave her an unusual position: it may be said that she helped the dawning 19th century to take stock of itself.

**BIBLIOGRAPHY.**—*Editions, etc.*: The first complete edition is by Auguste de Staël, her eldest son, with a "Notice" by Mme Necker de Saussure, 17 vol. (1820–21). Modern critical editions of separate works include *De la Littérature*, by P. van Tieghem, 2 vol. (1959); and *De l'Allemagne*, by Comtesse Jean de Pange, 5 vol. (1958–60).

**STAFF, MILITARY**, a term used to designate the officers who assist the commander of a military force. The basic meaning of the term is similar in all armies, though staff organizations and their functioning vary considerably. The staff is commonly distinguished from the "line," the purely combatant portion of the army. (For naval staff, see below.)

The staff assists the commander by performing the detailed duties of administration, planning, supply and co-ordination that are necessary to control and maintain his forces. It works out detailed plans in support of the commander's intentions, translates his decisions into orders and issues the orders to the troops. The staff is the commander's channel for maintaining contact with the subordinate units of his force and for receiving the information and advice he requires. A chief of staff normally heads the organization, which is divided into sections responsible for definite fields of activity, such as personnel, intelligence, plans and operations, training and supply. Staff officers have no command authority in their own right; they act always as agents of the commander, issuing orders in his name.

All modern armies, following a concept developed during the 19th century, employ some form of general staff. While the term has had various uses and often designates the staff of a general commanding any major unit of division size or greater, it most commonly denotes the staff of the central headquarters directing the nation's entire army establishment. Such a staff, usually located in the national capital, assists the officer in supreme command of the entire army in the performance of his functions. That officer is responsible to the government for all aspects of the readiness of the army for war, and usually for direction of the army's operations after hostilities have begun. Accordingly, the general staff in peacetime is concerned both with the training and administrative control of existing forces and with the preparation of plans for any war in which the nation might become involved.

### EARLY HISTORY

**Ancient and Medieval Armies.**—As warfare advanced beyond the type of tribal conflict in which a single chieftain could keep his entire force within sight and lead it with his own battle cry, the commander's need for assistants grew. The need was met in a variety of ways, but the institution of the military staff showed no consistent development prior to the Thirty Years' War (1618-48), when regularization of army organization along relatively modern lines began. Until that time, staffs were usually on an informal basis. The commander merely retained a group of officers as his personal party, calling on them for whatever service the moment required, such as reconnaissance or the delivery of orders.

Even in permanently organized formations such as the Roman legion, staff functions were not clearly defined. In the army of the Roman republic, six tribunes headed each legion. The actual command rotated among them, and the five tribunes not currently in command were available for staff duty. In the last days of the republic the legion came under the permanent command of a legate. The six tribunes remained as his assistants, but, with these positions held by men of less stature and experience than under the former system, the tribunes appear to have been little more than orderlies.

In the warfare of the feudal era, with its short campaigns and limited forces, military staff organization had no place. Staff development began when larger armies, representing the ruling dynasties of the emerging national states of Europe, took the field in the 16th and 17th centuries.

**Gustavus to Napoleon.**—By the early 1630s Gustavus Adolphus had developed the Swedish army into an exceptionally well-organized force. Composed of companies and regiments of uniform size, with a set hierarchy of officers, it had a supply system that functioned smoothly, its soldiers were regularly paid, and its activities were governed by written regulations upheld by courts-martial. While the assistants Gustavus gathered about him were still largely a group of individual officers rather than an organized staff, most of them were assigned titles and definite responsibilities, such as the provost marshal, the judge advocate and the quartermaster. The Gustavian military organization was widely copied, and, indeed, a substantial part of the Swedish king's army passed intact into the service of France a few years after his death in 1632.

Over the next century and a half in most European armies the duties of the quartermaster (*q.v.*) tended to expand until that officer took on many of the attributes of a modern chief of staff. The quartermaster's responsibility for quartering and feeding the troops centred his thought on what lay ahead—the direction and route of the next day's march, the selection, laying out and fortification of the next camp site, and the daily extension of the line of supply. In time that officer became responsible for reconnaissance, for directing marches and ultimately for drafting operational orders, in addition to his basic supply function.

In the French army developed by Richelieu and inherited by Louis XIV in the mid-17th century the emergence of a chief of staff had already begun. The army organization included several officers bearing the title *maréchal de camp*, who handled the quartermaster functions. In one of these, the *maréchal général de camp*, were centralized some of the duties of a chief of staff, serving the marshal of France who was conducting the campaign. At the same time there was a *maréchal de bataille*, who formed the army in battle array and directed its tactical movements. The latter officer soon passed from the scene, and by the end of the 17th century the chief of staff's position, now called the *maréchal général des logis*, had assumed some responsibility for operations as well as intelligence and supply.

In the Prussian army that Frederick the Great led in his campaigns of the mid-18th century, on the other hand, staff organization developed slowly in the presence of military genius. Frederick was, in effect, his own operations officer and chief of staff. He required few assistants but gave careful attention to their professional training. Recognizing a need for officers to perform reconnaissance, select and fortify camp sites and guide troops on the march, he personally chose and instructed 12 officers in these duties, adding them to his small quartermaster general's staff.

Frederick's interest in the intellectual preparation of officers for high-level duties led him in 1765 to establish an academy where young noblemen were trained in diplomacy and the military art. It was the forerunner of the *Kriegsakademie* that capped the educational system of the German general staff in the 19th century.

**Napoleon.**—By the time another military genius appeared in the person of Napoleon Bonaparte, the conditions of warfare had been altered in a way that allowed a larger place to military staff operations. The concept of the nation in arms that arose during the French Revolution produced mass armies several times larger than those commanded by Frederick a quarter of a century earlier, but there was also a striking increase in their mobility and maneuverability. Infantry, made more secure against cavalry attack by the socket bayonet and the increased firepower of the flint-lock musket, combined with the first really mobile field artillery to mark the end of the rigidly indivisible army. Napoleon organized his army into autonomous corps and divisions, capable of sustaining themselves when separated by a day's march or more. Dispersion of his units not only made it easier to live off the country but permitted rapid movement by the use of parallel roads.

Command centred in the person of Napoleon himself. He required all intelligence reports to be delivered directly to him, and he sought no staff advice when devising his plans and instructions. But a staff was needed to keep track of the disposition of the corps and divisions and to translate Napoleon's decisions into written

orders that would set the subordinate units into co-ordinated motion toward the accomplishment of his design. For these relatively technical staff duties Napoleon had an able practitioner in his chief of staff, Marshal Louis Alexandre Berthier.

A studious soldier and a tireless master of detail, Berthier had reduced to writing his conception of ideal staff organization and functioning as early as 1796. More influential in generating thought and study on the subject was the manual of staff doctrine and procedure published in 1800 by another French staff officer, Paul Thiébault, which was soon reproduced in English, German, Russian and Spanish. Both writers stressed the requirement for speed in staff work and for accuracy and conciseness in the writing of reports.

#### DEVELOPMENT TO WORLD WAR II

**General Staff.**—Warfare had developed during the Napoleonic era into a complex activity that engaged the full efforts and resources of nations. The work of the military staff consequently rose from the level of planning the next day's march to a more comprehensive form of activity. The 19th century saw the emergence of the concept of the general staff as an organization that prepared war plans in peacetime and systematically collected information that would be useful in the future conduct of operations. In most countries the first activity of this type was topographical reconnaissance and surveying for the production of military maps, because with greater mobility and dispersion of units, generals found it necessary to conduct war on the map rather than by direct observation of the field. The information gathered soon included all that could be learned about the army and military resources of every potential enemy state. The general staff became concerned as well with the intellectual preparation of officers for command and staff duties, through historical study, war games, field maneuvers and attendance at staff colleges.

**German Staff System.**—The general staff system developed in the Prussian army was the first and for many years the most successful. Extended as the German general staff when the Prussian king became the emperor of a unified Germany, it profoundly influenced the development of modern military staffs in other armies during the years through World War I.

The Prussian general staff took form around the small quartermaster general's staff used by Frederick the Great, which had gained some additional functions under his successor and in 1796 had been directed to prepare a complete military map of Prussia. Under the influence of an energetic lieutenant quartermaster general, Col. Christian von Massenbach, the staff after 1801 passed beyond the mere gathering of geographical information and began formulating a somewhat theoretical set of plans for possible operations.

The enduring development of the general staff began with Gerhard von Scharnhorst's (q.v.) reorganization of the Prussian army following its defeat at Jena in 1806. In form the staff was little changed from Massenbach's day, but Scharnhorst introduced features that kept staff officers in close touch with the commanders and troops and prevented them from living in a world of theory. Under his system officers were selected from all branches of the army to serve on the general staff, and they returned periodically to regular duty with the troops. In addition to maintaining their practical proficiency as soldiers, this rotation permitted a greater number of officers to gain experience in general staff duties, qualifying them for staff assignments when war increased the size of the army.

With the final defeat of Napoleon in 1815, the main body of the Prussian general staff was concentrated in Berlin as the "great general staff," distinguished from the officers of the "general staff with troops," who served in vital staff positions in corps and division commands. In 1821 the two elements of the general staff were placed under a single chief of the general staff, who was thereafter the supreme professional military head of the Prussian army. At the same time, the Prussian king removed the general staff from the control of the war ministry and made it directly responsible to the sovereign.

Thereafter the general staff developed under the leadership of

a succession of able chiefs, most of whom held the position for extended periods. Count Helmuth von Moltke (q.v.), serving from 1857 to 1888, was the most distinguished. The master plans for speedy mobilization and strategic deployment of the Prussian forces produced by the general staff under his direction led to the rapid victories over Austria in the Seven Weeks' War of 1866 and over France in 1870. Success owed much to Moltke's quick appreciation of the importance of railways as a new factor in warfare. Full exploitation of their potentialities allowed him to deploy the army for war under a plan whose precision and reliability rivaled that of the railroad timetable itself.

To neighbouring countries the effectiveness and efficiency of the German general staff constituted both a menace and a model. During the last half of the 19th century all major nations on the European continent instituted or matured some form of general staff to make detailed plans for war in time of peace. Italy and Austria-Hungary closely followed the German system, and its influence on Russian staff development was marked. During the same period the rising power in the far east, Japan, adopted a high command and staff system that virtually duplicated the German.

Meanwhile in the German government the general staff attained a unique position of power that lasted through World War I. Fortified by the prestige of its victories and protected from civilian control and effective parliamentary questioning by its confidential relationship to the kaiser, the general staff frequently wielded great influence in the selection of ministers and the formulation of foreign policy.

**French Staff System.**—Attempting to meet the need for a system that would be effective in the absence of a self-sufficient military genius of Napoleon's type, Marshal Gouvion Saint-Cyr as minister of war made a promising beginning toward the creation of a professional staff corps in 1818. He established the *corps d'état-major*, which was to supply officers to staff the headquarters of all units of the French army, drawing its members from the graduates of a newly founded staff college. Saint-Cyr's wise provision that at successive stages in their careers staff officers should perform regular tours of line duty with the troops was abandoned in 1833, and the staff corps became a closed service. Restricted membership, a rather narrow type of training and permanent assignment to staff duties tended to separate the staff corps from the main life of the army and even generated some distrust and disdain of its services by field commanders. Weakness in staff work and in comprehensive planning for war ranked high among the reasons for the French defeat in 1870-71.

During their remarkable period of national resurgence following the Franco-Prussian War the French soon came to emulate, if they did not directly copy, the German general staff system that had designed their defeat. By the 1880s they had replaced the former staff corps with a true general staff, headed by a chief titled the *chef d'état-major général de l'armée*. Staff candidates passed through an advanced school, the *École Supérieure de Guerre*, and alternated thereafter between staff assignments and regimental duty.

By 1914 France had a highly proficient general staff that was employed, like its German counterpart, in keeping a prepared file of campaign and mobilization plans up to date while overseeing all other aspects of the readiness of the army for war. Staffs at all levels in the French army were organized, under their chief, into three bureaus. The first bureau handled both supply and administrative matters such as recruitment, organization of units, casualty reports and the assignment, promotion and discipline of personnel. Enemy information was the concern of the second bureau, while the third prepared orders for military movements and operations.

The continuous combat operations of World War I, differing from the set battles of the past, brought the creation of a fourth bureau that assumed responsibility for the duties of supply, transportation and casualty evacuation formerly held by the first bureau. Thus the French system that matured during World War I displayed a distinct separation of staff functions into categories of administration, intelligence, operations and supply. It continued in this form without substantial change in later years.

**Russian Staff System.**—Imperial Russia was another country where military staff institutions took form around the expanding responsibilities of the quartermaster. Peter the Great appointed the first quartermaster general, in 1701, and the duties of that office grew steadily during the 18th century, often in imitation of the Prussian model. By 1815, when Tsar Alexander I established the "Headquarters Staff of his Imperial Majesty," the quartermaster general's section was the main staff component, responsible for most aspects of military operations. At the recommendation of Baron Antoine Henri Jomini (*q.v.*), formal education of officers for staff duties began with the founding of the Nicholas academy in 1832.

Reorganizations in which the influence of the German general staff concept was apparent followed both the Crimean War (1853-56) and the Russo-Japanese War (1904-05). The imperial Russian army entered World War I under a general staff immediately subordinate to the minister of war—a directing system that appeared to be as well appointed as any other on the continent. That there had been no proper staff training, however, became apparent when the deficiencies soon revealed in staff planning for the supply of the fighting forces contributed greatly to the disorganization and defeat that prepared the way for the Revolution of 1917 and the dissolution of the imperial army.

The Red army was brought into existence in 1918 to defend the new Bolshevik government against counterrevolutionary forces and foreign invaders. To provide their army with competent leadership the Communist masters found it necessary to enlist many former officers of the imperial army, particularly general staff officers and instructors for the military schools. As a result, staff doctrine and organization tended to remain unchanged, and most of the elements of the old general staff continued to function under the new commissariat of the army and navy. Moreover, the traditional German influence was renewed when Soviet officers began receiving training in Berlin military academies following the treaty of Rapallo in 1922.

One notable innovation was the commissar system, which placed a political officer on the staff of every Red army commander to monitor his activities and insure loyalty to the Communist regime. Since no operational order was valid until countersigned by the commissar, he was virtually the equal of the military commander. After 1934 the commissar served only as supervisor of the morale and political indoctrination of the troops, but his cocommander status was restored for a period after the great purge of the military command in 1937 and following the German invasion of June 1941. The commissar was again reduced to the role of political adviser and propagandist in Oct. 1942, and Red army units came under the single direction of their professional military officers. The Red army staff reached a high standard.

**British Staff System.**—Since Great Britain had failed to keep step with 19th-century developments on the continent, the British army entered World War I with only a decade of experience in the operation of a general staff system. In a period when military thought had centred largely on defense of the British Isles against invasion and the problems of India and other distant colonies, staff development had been slow, despite the founding of a staff college in 1858.

Interest in army reforms began to quicken following the publication in 1890 of *The Brain of an Army* by an Oxford lecturer, H. Spenser Wilkinson. His book explained the importance of the general staff in the successes of the German army and underscored the need for introduction of a similar system in Britain. Pronounced deficiencies in the British command and staff system revealed during the Boer War completed the argument. In 1904 the report of Lord Esher's committee investigating the war office demanded the formation of a general staff, "as the term is understood in all well-organized armies." The position of chief of the general staff was created in that year, the general staff itself being formally constituted in 1906. With expanded functions, the title was changed in 1909 to chief of the imperial general staff.

British staffs in all major army units during both World Wars I and II were divided into three branches. One, called the general staff, handled intelligence and the planning and conduct of opera-

tions. The adjutant general's (A) staff dealt with personnel and administration, while the quartermaster general's (Q) staff managed supply and transportation. Broadly stated, the general staff section was concerned with the use of the army while the other two branches looked after its maintenance. The chief of the general staff section co-ordinated the work of the entire staff, collaborating with the chief administrative staff officer, who supervised both the A and Q branches. Only the headquarters of the largest formations employed separate chiefs of staff to head the whole organization.

**U.S. Staff System.**—Before 1903 there was no general staff in the United States army. The term was sometimes used, but merely as a collective designation for the army's generals and the officers whose assignment to engineer, ordnance and other duties set them apart from the infantry, cavalry and artillery. An officer titled the commanding general of the army had authority over the troops but not over the quartermaster, adjutant general and chiefs of the other technical and administrative bureaus of the war department, whose activities were vital to the successful operation of his forces. Each bureau chief, supreme authority in his own field, reported only to the civilian secretary of war. How little this unco-ordinated system was geared to actual preparation for war was indicated by the statement of the commissary general that his office was functioning perfectly until the Spanish-American War disrupted and disorganized it.

The striking administrative failures of the Spanish-American War revealed the inadequacy of the bureau system and opened the way for reforms under a new secretary of war, Elihu Root. He founded the Army War college in 1902 and the following year obtained from congress authorization to create a general staff. Root's carefully reasoned explanations of the purpose of a general staff, based partly on his reading of *The Brain of an Army*, overcame the fears of some legislators that the change would result in "Prussianization" of the U.S. army. The legislation of 1903 established a chief of staff immediately under the secretary of war and the president, and gave him both the responsibilities of the former commanding general of the army and supervisory authority over the bureaus. To comprise the new general staff corps, officers were selected from the army at large for duty on the war department general staff or on the staffs of field commanders as members of "the general staff serving with troops." Since its beginning the U.S. army general staff corps has been manned by rotation rather than permanent assignment.

As leader of the American expeditionary forces in France in 1917, Gen. John J. Pershing studied British and French organization before erecting his own staff structure. Its final form closely resembled the French, including a chief of staff and five sections devoted to personnel, intelligence, operations, supply and training. When Pershing became chief of staff of the army in 1921 he re-organized the war department along the lines of his World War I headquarters, retaining the "G" system of designation borrowed from the French. The five divisions, each headed by an assistant chief of staff, were called personnel (G-1), military intelligence (G-2), operations and training (G-3), supply (G-4) and the war plans division. This establishment underwent no basic change until the United States entered World War II.

## WORLD WAR II AND AFTER

**Joint and Combined Staffs.**—World War II, truly global in scope and fought by coalitions of great and lesser powers, presented problems of co-ordination and direction that called forth new, higher levels of command and staff organization. The war of 1939-45 saw the rise of air power to full stature as a third armed force, coequal with sea and ground power. Amphibious operations, in which the efforts of all three forces were joined, proved to be a major feature. Thus a controlling organization was needed to encompass both interservice and inter-Allied co-ordination.

As the supreme military body for the strategic planning and direction of the Allied war effort in all areas except the Soviet front, the United States and Great Britain established the combined chiefs of staff early in 1942. Located in Washington, D.C., the combined chiefs of staff organization was directly responsible to the U.S. president and the British prime minister as a combined

executive. The three British services were represented by the first sea lord, the chief of the imperial general staff and the chief of the air staff. Within the British government these three offices had been joined since 1923 as the chiefs of staff committee, bearing a corporate responsibility for the command and strategic direction of United Kingdom forces and for supplying military advice to the cabinet and prime minister.

To provide United States membership on the combined chiefs of staff to match this British representation, a new agency known as the joint chiefs of staff came into existence in the U.S. The title followed an agreed definition of terms whereby "combined" signified collaboration between two or more of the Allied nations while "joint" was used to designate the interservice collaboration of one nation. The original members of the U.S. joint chiefs of staff were the army chief of staff; the naval officer holding the double title of commander in chief, U.S. fleet, and chief of naval operations; and the commanding general of the army air forces. Later in 1942 an officer serving as chief of staff to the president became the fourth member.

Beneath the combined chiefs of staff was a planning organization that operated on the committee principle. Combined committees for strategic planning, logistics, intelligence, munitions assignment and other purposes were manned by army, navy and air force staff officers drawn in equal numbers from the two nations.

In March 1942 a reorganization of the U.S. war department increased the effectiveness with which the general staff supported the army chief of staff in his expanding duties at the joint and combined levels. Redesignated the operations division, the former war plans division became the agency through which the chief of staff exercised command authority over the widely deployed forces of the army. The four "G" sections of the general staff concerned themselves only with the development of broad policy, since responsibility for training, the actual operation of the supply system and such technical services as the ordnance, medical and signal branches had been decentralized to three subordinate commands: the army ground forces, the army air forces and the army service forces.

Anglo-U.S. unity in the higher direction of the war was reflected in the field, where forces of both nations were placed under the single authority of a supreme commander with a combined staff. The principle found its fullest expression in the two staffs commanded by Gen. Dwight D. Eisenhower in his Allied force headquarters (AFHQ) in Africa and his supreme headquarters, Allied expeditionary force (SHAEP), in Europe, where officers of the two nations were completely integrated.

The SHAEP staff followed U.S. doctrine in its basic organization, with assistant chiefs of staff for personnel (G-1), intelligence (G-2), operations (G-3), supply (G-4) and civil affairs (G-5). The G-1, G-3 and G-4 staff chiefs were American, while British officers headed G-2 and G-5, but each chief had a deputy of the opposite nationality. In Gen. Walter Bedell Smith the Americans provided an able chief of staff, who was supported by three British deputies. One deputy handled air matters; the responsibilities of the other two followed the usual British division between operations and intelligence functions on the one hand and the "A" and "Q" administrative functions on the other.

In contrast to the western Allies, Germany was poorly organized to deal with its relatively simpler problems of co-ordination. In theory the *Oberkommando der Wehrmacht* (OKW), or armed forces high command, corresponded to the U.S. joint chiefs of staff or the British chiefs of staff committee as the agency for strategic direction and co-ordination of the three services. In practice OKW was dominated by the army and was not a true joint staff. Its control over the armed forces was slight, since the heads of the air force and navy stood in a favoured relationship to Hitler, while the dictator himself assumed control of the army through its high command staff, the *Oberkommando des Heeres* (OKH). Rather than being the supreme military authority, OKW came to be roughly coequal with OKH, controlling German operations in the west while OKH dealt with the Russian front.

When invaded by Germany in 1941, the Soviet Union quickly redesigned its highest governing agencies for centralized control

of the war effort. Stalin assumed personal direction of military operations, gathering under himself a supreme headquarters called the *stavka*. Composed of about 20 top military officers of various arms, the *stavka* developed over-all strategic plans for Stalin's approval. The chief of the general staff was a member, and his organization served directly under the *stavka*, providing information and working out detailed operational plans and orders to implement the approved strategy. Normally these operational orders were transmitted to the front commanders for execution, but the *stavka* occasionally detached a command group from its own membership to conduct a particular campaign.

**Trends After World War II.**—Continuation and elaboration of the unified command and joint staff practices initiated during World War II marked the postwar period. In the United States, the National Security act of 1947 made the air force a separate service but placed it with the army and navy under a single department of defense. The act also gave legal recognition to the wartime joint chiefs of staff (JCS), provided them with a full-time joint staff, and designated the joint chiefs of staff the principal military advisers to the president and the secretary of defense. Amendments in 1949 made them the military advisers to the National Security council as well. Composed of the army chief of staff, the chief of naval operations and the air force chief of staff, JCS after 1949 had a fourth and senior member called the chairman. In most areas where U.S. forces were stationed, JCS set up a unified command in which a single commander with a joint staff controlled units of all three services.

Great Britain also consolidated its wartime experience by making the ministry of defense a permanent office in 1946, with authority over the three services. At the beginning of 1956 the British chiefs of staff committee, like JCS, received a chairman as its fourth member.

In the Soviet Union during 1946 the wartime *stavka* was disbanded and a single ministry of the armed forces assumed control of military affairs. A division into ministries of war and navy occurred in 1950, but the services were united again in 1953 under the ministry of defense. The general staff served directly under the minister of defense, and its chief was one of his deputies. The general staff was basically the former Red army general staff, elevated to responsibility for military planning and co-ordination applicable to all the Soviet armed forces.

New circumstances brought forth new varieties of international staffs, resembling the Anglo-U.S. combined chiefs of staff of World War II. The 12 nations signatory to the North Atlantic treaty agreed in 1949 to set up regional military committees in which as many as five countries would be represented. Under the treaty an extensive international staff organization was created at the supreme headquarters, Allied powers in Europe (SHAPE).

(V. E. D.)

**Naval Staff.**—There is no general staff corps in the Royal Navy or the U.S. navy to resemble the general staff corps in various armies. Service opinion has always been strongly against such a corps, but both navies have attempted to educate officers for staff duties without designating them as specialists. The U.S. navy established the Naval War college at Newport, R.I., in 1884, the first institution of this kind. The Royal Navy has a naval war college and a naval staff college as components of the Royal Naval college, Greenwich. Through the efforts of men like Adm. Sir Herbert W. Richmond, the attempt was made to foster the scientific study of war, to develop logical and consistent habits of thought in connection with the employment of naval force in war and to emphasize that matériel alone will not win wars. Both the Royal Navy and the U.S. navy have always stressed professional competence in seamanship, but Adm. Stephen B. Luce (*q.v.*), who founded the U.S. Naval War college, Adm. Alfred Thayer Mahan (*q.v.*), who succeeded Luce as head of the War college, Admiral Richmond and other British and American officers attempted through their writing and teaching to bring naval staff work up to the high standards of seamanship which prevailed already. The officers who do the naval staff work in Whitehall, and on the staffs of British admirals, as well as those who do such work in the navy department, and on the staffs of American

admirals, are assigned to the admiralty or to naval operations: or to a seagoing staff for a period of not more than three years, after which they take some other assignment. Thus the staff work is done by seagoing officers fresh from a nonstaff billet who expect to return to duties which might involve responsibility for executing basic plans which they have helped to formulate while serving on the naval staff.

The first sea lord is chief of the British naval staff. He is assisted by a vice chief of staff and two deputy chiefs of staff, all flag officers. The naval staff is located in the admiralty office and is directly responsible for intelligence, planning, operations and tactical doctrine. In addition, there are staff divisions which advise on the policy concerning training in all its aspects, and on the requirements for new ships, aircraft and weapons.

In the United States the chief of naval operations is the naval member of the joint chiefs of staff organization. He heads what is, in fact, the naval staff of the U.S. navy, although it does not bear that name. The naval operations organization performs the naval staff duties, as well as day-to-day administrative functions, much the same as does the admiralty in London. (J. B. HN.)

**STAFFA** (Norse for staff, column or pillar island), uninhabited island of the Inner Hebrides, Argyll, Scot., 33 mi. W of Oban, about 6 mi. NE and SE from the nearest points of Mull and 6 mi. N by E of Iona. It lies almost due north and south, is  $\frac{3}{4}$  mi. long by about  $\frac{1}{2}$  mi. wide, and its highest point is 144 ft. above sea level. In the northeast it shelves to a shore, but otherwise the coast is rugged and much indented with numerous caves. During the tourist season it is visited regularly by steamer from Oban. In section the isle has first a basement of tufa, from which rise, secondly, colonnades of basalt in hexagonal pillars forming the faces and walls of the principal caves which in turn are overlaid, thirdly, by a mass of amorphous basalt. On the southeast coast is the Clamshell, or Scallop Cave. It is about 130 ft. long, and on one side of it the ridges of basalt stand out like the ribs of a ship. Near this cave is the rock of Buachaille ("The Herdsman," from a supposed likeness to a shepherd's cap), a pile of columns, fully seen only at low water. On the southwest shore are the Boat Cave and Mackinnon's, or the Cormorant's, Cave. Fin-gal's Cave (q.v.), the most famous, situated in the southern face of the isle, is 227 ft. long. On its western side the pillars are 36 ft. high. The cave is the haunt of seals and sea birds.

**STAFFORD**, the name of a famous English family that at different times from the 13th to the 17th century held the titles of Baron Stafford, earl of Stafford, and duke of Buckingham. The family was founded in England by ROBERT (d. c. 1088), a younger son of Roger de Toeni, the standard-bearer of the duchy of Normandy. After the Norman Conquest Robert received a great fief extending into seven Midland counties and became known as Robert de Stafford from his large holdings in Staffordshire. On the death of his great-grandson ROBERT (d. 1193/4) the male line became extinct. This Robert's sister MILICENT (d. 1225) had married one of Robert's vassals, Hervey Bagot, who succeeded in the fief in her right and assumed the name de Stafford. Their great great-grandson EDMUND (1273–c. 1308) was summoned to Parliament as Baron Stafford in 1299. His son RALPH (1301–72) in 1346 was prominent at the defense of Aiguillon and at Crécy. He was made a knight of the Garter (c. 1348) and was created earl of Stafford in 1351.

His son HUGH (c. 1342–86), 2nd earl, was one of the 12 peers appointed during the Good Parliament (1376) to confer with the Commons on their grievances. Hugh's son THOMAS (c. 1368–92),

3rd earl, married Anne, daughter and heiress of Thomas of Woodstock, duke of Gloucester, the youngest son of Edward III. The 3rd earl's brother WILLIAM (1375–95), 4th earl, died a minor and was succeeded by another brother EDMUND (1378–1403), 5th earl, who married the 3rd earl's widow, Anne. Edmund was appointed to the office of constable of England in 1403 by virtue of its hereditary descent through Anne's mother, Eleanor Bohun. His son HUMPHREY (1402–60), 6th earl, was created duke of Buckingham in 1444, and in 1447 was granted precedence "before all dukes who might thenceforth be created, excepting descendants of the king's body."

HENRY (1455–83), 2nd duke (see BUCKINGHAM, HENRY STAFFORD, 2nd Duke of), grandson of Humphrey, was beheaded and attainted for rebelling against Richard III. Henry's eldest son, EDWARD (1478–1521), 3rd duke, was restored to the family lands and title by act of Parliament in November 1485 after the accession of Henry VII. He was beheaded for treason (1521) against Henry VIII, and his attainder was confirmed by act of Parliament in 1523. His only son, HENRY (1501–63), married (1519) Ursula, daughter of Sir Richard Pole by Margaret, daughter of George, duke of Clarence, and niece of Edward IV and Richard III. He was restored in blood after Edward VI's accession and declared Baron Stafford in a new creation in 1547.

Henry's son HENRY (c. 1533–66) became 2nd baron. His next brother, THOMAS (c. 1534–57), opposed the marriage (1554) of Mary I to Philip (later Philip II) of Spain and plotted against her from France. Claiming to be heir to the throne by royal descent from both of his parents, he seized Scarborough Castle in Yorkshire (April 1557) but was captured and executed for treason. His younger brother, EDWARD (1536–1603), 3rd baron, was a judge at the trial of Mary Stuart in 1586. Edward's great-grandson HENRY (1621–37), 5th baron, died unmarried, and the barony passed to his impoverished cousin and male heir ROGER (1572/5–c. 1640), the only son of RICHARD, youngest son of the 1st baron. Roger surrendered the barony to Charles I in 1639 for £800. When he died unmarried the direct male line of the Staffords became extinct. Charles I bestowed the title in 1640 on MARY (c. 1619–94), sister of the 5th baron, and on her husband William Howard, fifth son of the 14th earl of Arundel, in whose descendants the barony is now vested.

**STAFFORD**, a market town, municipal borough, and the county town of Staffordshire, Eng., is situated on the River Sow in the green belt separating the industrial areas to the north and south of the county. Pop. (1961) 47,806. Public buildings include the Shire Hall (1798–99), Borough Hall (1876–77), Guildhall (1934), and the Municipal Central Library, with an art gallery and museum (1914). The County Technical College, the College of Art, and the county administrative buildings are also in the borough. Chetwynd House (now the post office) was associated with Richard Brinsley Sheridan, dramatist and member of Parliament for Stafford from 1780 to 1806, and the Swan Hotel with Charles Dickens and George Borrow. The half-timbered "High House" was built in 1555, and the Martin Noel almshouses are also Elizabethan. St. Chad's Church was founded in the reign of Stephen, and St. Mary's parish church, Early English and once collegiate, adjoins the site of the Saxon church of St. Bertelin, patron saint of Stafford, which was excavated in 1954 and is now outlined in the original stone. In Eastgate is the reputed birthplace of Izaak Walton, whose cottage at Shallowford, 4 mi. (6.4 km.) outside, is now a Waltonian museum.

Founded by Aethelflaed, daughter of Alfred the Great, Stafford had its own mint from the reign of Aethelstan to that of Henry II. William the Conqueror built a castle there and appointed as governor Robert de Toeni, baron de Stafford. During the Civil War, Stafford declared for the king, but in 1643 the town was occupied by Parliamentarians, who demolished the town walls and castle (a replica begun in 1810 is now in ruins). Granted its first charter in 1206 by King John, Stafford returned two members to Parliament from 1313 to 1885, and thereafter only one.

Stafford lies on the London-Birmingham-Manchester route by road and rail. Industries include electrical engineering, reinforced concrete structures, adhesives, grinding wheels, locomotives, diesel

engines, salt, shoes, and footwear machinery. (M. P. D.)

**STAFFORDSHIRE**, a midland county of England, is bounded north by Cheshire and Derbyshire; east by Derbyshire, Leicestershire, and Warwickshire; south by Warwickshire and Worcestershire; and west by Shropshire and Cheshire. Its geographical area is 1,154 sq.mi. (2,989 sq.km.).

**Physical Features.**—Of the five physical regions of the county, the Pennine northeast uplands belong to highland Britain; and the Potteries coalfield, the central agricultural belt, Cannock Chase, and the South Staffordshire coalfield to lowland Britain.

The northeast uplands, between 800 and 1,500 ft. (about 240 and 460 m.), consist of folded north-south ridges of Millstone Grit and areas of Carboniferous Limestone, both of which are deeply incised to form bold scars by the Dove, Churnet, Hamps, and Manifold rivers, the headstreams of the Mersey and Trent. Much of the bleak treeless limestone area was in 1951 designated part of the Peak District National Park. To the southwest is the triangular-shaped Potteries coalfield, cut into by the River Trent and composed of sandstones, clays, and shales, with coal seams. To the west and south the coal dips below the sandstones. The central agricultural belt consists of Triassic rocks and is drained by the Trent. The undulating land of Bunter and Keuper sandstones, which adjoins the south of the Potteries coalfield and the uplands, extends along the county's western margin. It is upfaulted in a north-south ridge east of Stafford and extends to the southern boundary of the county to the east and west of the South Staffordshire coalfield. It also forms Cannock Chase; at about 600–700 ft. (180–210 m.) this barren heath was formerly part of a royal forest and today is an attractive amenity north of the Black Country communities. Apart from these sandstone areas, the centre of the county is occupied by the heavy soils and rather featureless landscape of the Keuper marls, which, reaching from north of Uttoxeter to Tamworth in the east, extend westward in a broad belt across the county. The South Staffordshire coalfield is a drift-capped plateau that forms part of the main east-west watershed in central England; drainage is by the River Stour to the Severn on the west and to the Trent on the east. The coalfield consists of ridges and low hills at about 400–500 ft. (120–150 m.), which are the sites of such towns as Wednesbury. The Rowley Hills, of igneous intrusive rock and the earlier Silurian shales and limestones, link together to form a ridge of highland from Rowley Regis to Wolverhampton.

**History.**—Traces of Neolithic man and his Bronze Age successors remain, especially in the northeast. Of the Iron Age, hill-top forts at Castle Ring on Cannock Chase and at Bury Ring near Stafford are probably the most notable. The Romans cut important roads through the forests that covered the country, notably Watling Street, running roughly east-west across what became later the southern part of Cannock Forest, and Ryknield Street, running south-southwest, which intersected Watling Street at Letocetum (Wall) near Lichfield. Farther west at Pennocrucium (near Penkridge) was another military station on Watling Street.

From the 7th to the 9th century the kingdom, and in the 10th to 11th centuries the ealdormanny, of Mercia had its centre in this area. Tamworth was the royal city of Mercia; Lichfield, soon after the region's conversion to Christianity, became its diocesan centre in 669. Between 873 and 874 the Danes ravaged the area, but evidence of permanent settlement by them is slight except on the eastern boundary where the present county adjoins what became known as Danelaw. Nevertheless, much of it then lay within the area assigned to the Danes by the treaty of about 886. From 910, when Edward the Elder defeated the Danes at Tettenhall, he and his sister Aethelflaed, "Lady of the Mercians," reconquered the area, building fortified enclosures (boroughs) at Tamworth and Stafford in 913. Renewed fighting with the Danes at the end of the 10th century caused further damage, and the first reference to Staffordshire as such tells of its ravaging in 1016.

The county as revealed by Domesday Book toward the close of the 11th century was divided into five hundreds, or subdivisions: Totmanslow, Pirchill, Offlow, Cuttlestone, and Siesdon. Much of it was sparsely populated and poor, a state of affairs to which its devastation by William the Conqueror following the rising of

1069–70 doubtless contributed. At that time the crown and the church were the dominating landholders, and, although by the late Middle Ages the Stafford dukes of Buckingham (descendants of another 11th-century Staffordshire landholder) had acquired great local and national influence, the crown retained its immediate importance in the county by the acquisition in 1399 (on the accession of Henry IV) of the property of the duchy of Lancaster. The large crown estates and the normal support given in the 15th century to the Lancastrians by the dukes of Buckingham ensured that, at any rate during the first phase of the Wars of the Roses, most Staffordshire influence supported them rather than the Yorkists. During Queen Elizabeth I's reign it became clear that many influential adherents of Catholicism remained in the county, although this did not prevent the earl of Shrewsbury, appointed custodian of Mary Stuart, from keeping her for short periods at Tutbury Castle and at his house at Chartley. It was the Roman Catholic gentry who added considerably to the support received in Staffordshire by the Royalists during the Civil War (1642–51). Nevertheless, the Parliamentary committee at Stafford gradually established control of the whole county, in which, apart from a battle upon Hopton Heath (March 1643), the fighting was largely confined to sieges like those of Lichfield Close. Charles II's flight after the Battle of Worcester (1651) took him to hiding places at Boscobel, Moseley Old Hall, and Bentley Hall.

Staffordshire's later history is largely that of its industries, though coal and iron have been worked from at least the 13th century. The 16th century probably saw an increase in production of both industries. In coal mining this was accompanied by the use of somewhat deeper mines, while at Cannock Wood and Oakmoor blast furnaces were built instead of the older bloomsmithy. Historical documents give a vivid picture of the development of these undertakings, as well as social and industrial conditions among the blacksmiths, nailers, and spurriers in the south of the county. Other industries that developed in this and subsequent periods included glassmaking in the southwest and near Eccleshall and copper works near Cheadle. In the north of the county around Stoke-on-Trent during the 18th century, the long-established pottery industries achieved a national and then a worldwide market. The brewing industry at Burton upon Trent developed a similar reputation in the 19th century. It was potters like Josiah Wedgwood, and then other industrialists, who were the driving force behind turnpike road and canal schemes and who in the next century gave the county a network of railways.

By the 19th century the Potteries and the Black Country (*qq.v.*), with nearby Birmingham, had become major industrial areas, important for the social and economic problems they posed, for the religious and social thought to which these gave rise, as well as for the goods manufactured in these regions.

Prominent Staffordshire people have included Izaak Walton; Samuel Johnson; James Brindley, the canal builder; Hugh Bourne, the founder of Primitive Methodism; the admirals Lord Anson and Lord St. Vincent; the actor and playwright R. B. Sheridan, who was member of Parliament for Stafford, and David Garrick.

**Population and Administration.**—The area of the administrative county is 1,071 sq.mi. (2,774 sq.km.) and its population (1961) 985,113. There are 6 county boroughs, 8 noncounty boroughs, 17 urban districts, and 10 rural districts. Lichfield and Stoke-on-Trent are cities. Old market towns include Abbots Bromley, Brewood, Cheadle, and Eccleshall. The county is in the Oxford Circuit, and assizes are held at Stafford. There is one Court of Quarter Sessions and 20 petty sessional divisions. Stafford and Wednesbury have separate commissions of the peace, while Lichfield, Newcastle-under-Lyme, and the county boroughs have separate courts of quarter sessions as well. The county boroughs are Stoke-on-Trent (pop. [1961] 265,306), Wolverhampton (150,825), Walsall (118,498), Smethwick (68,390), Burton upon Trent (50,751), and West Bromwich (96,041) (*qq.v.*). The municipal boroughs are Lichfield (14,087), Newcastle-under-Lyme (75,688), Stafford, the county town (47,806), Tamworth (13,646), Wednesbury (34,511), Bilston (33,067), Rowley Regis (48,146), and Tipton (38,100) (*qq.v.*).

The moorlands are still sparsely populated, though the growth of road transport has reduced their isolation. The industrial towns, particularly of the Potteries and the Black Country, have much poor housing and ravaged land as a legacy of the 19th century, but developments since World War II have included attempts to relieve the congested population by overspill and to reclaim the large areas of desolate and derelict land for redevelopment.

In 1962 the University College of North Staffordshire, founded at Keele in 1949, became the University of Keele.

**Industries and Communications.**—William Camden in the 16th century remarked on the richness of the grazing lands, and, despite industrial development, about 75% of the land is agricultural, Staffordshire being in the main a dairying county. The rough pasture and grass of the moorlands give way to mixed general and dairy farming along the Cheshire and Shropshire borders. On the other side of Cannock Chase is the mideastern region of grassland. Arable land to the south includes market gardens round Lichfield and Tamworth, where, in contrast to the predominance of fodder crops in the rest of the county, these are outweighed by wheat, potatoes, sugar beets, and vegetables. The Forestry Commission grows timber on Cannock Chase and in 1964 owned 12,566 ac. (5,086 ha.) in the county. Chartley Moss is a national nature reserve, and in 1964 the National Trust owned 1,783 ac. (722 ha.) in Staffordshire; 1,773 ac. were protected.

Of the iron ore and coal deposits on which the Black Country's industries were founded, the iron supply has been exhausted, and coal mining is now largely confined to the northern fringe of the area and to Cannock Chase. Nevertheless, the area retains its importance for the great volume of its manufactures, both hardware and engineering products. It consists of a number of towns, most of which, whether large like Wolverhampton and Walsall, smaller like Willenhall, or villages like the Gornals, have their own industrial tradition. The Potteries, besides their earthenware and china products, share with Newcastle-under-Lyme and other smaller towns in the neighbourhood extensive coal and iron industries. Towns like Stafford have large engineering and shoe works; Stone has a shoe and glass factory; Armitage makes sanitary ware; Leek produces silk and rayon; Tamworth manufactures paper; and Burton upon Trent is famed for its beer. Gravel workings and stone quarries are widespread, especially in the moorlands near Caudon and at Hollington.

The greater part of the railway network is operated by the Midland region of British Railways. The main line from London to Crewe runs through Tamworth, Lichfield, and Stafford, while the Birmingham line passes through Wolverhampton and joins the London-Crewe line at Stafford. The Western Region Birmingham to Shrewsbury line passes through Wolverhampton, which also has an airport.

The county's canals include those in the Birmingham system; the Trent and Mersey Canal, built by James Brindley in 1766–77; and the Shropshire Union.

**STAGE**, in architecture, an elevated floor, particularly the various stories of a bell tower, etc. The term is also applied to the plain parts of buttresses between cap and cap where they set back, or where they are divided by horizontal strings and paneling. It is, too, the floor or platform on which plays are acted, whence the term has come to signify both the theatre and the drama (*q.v.*; see also **STAGE DESIGN**). From its etymological meaning of a station comes the sense of a place for rest on a journey, the distance between such places, etc. See also **THEATRES (STRUCTURES)**.

**STAGE DESIGN** is the art of creating scenery for theatrical performances. It takes into consideration such elements as cos-

tuming, lighting, and stage machinery, and also the question of theatrical style, where the sphere of the designer merges with that of the director. This article outlines the history of stage design and concludes with an account of modern practice. Familiarity with the articles **ACTING**, **DIRECTION** and **PRODUCTION**; **DRAMA**; and **THEATRE** will enhance the reader's grasp of the subject, and he may wish to refer frequently to **THEATRES (STRUCTURES)** on matters of detail. Costuming is treated separately in the article **COSTUME DESIGN**; **THEATRICAL**. Stage lighting—a highly specialized craft belonging mainly to the modern era—is here discussed in relation to stage design as a whole; for detailed history and more technical aspects, see **STAGE LIGHTING**.

12. Socialist Realism
13. Epic Theatre

#### II. Contemporary Stage Design

1. Stage Equipment
2. Principles of Design
3. Working Out the Design
4. Scenery Construction
5. Scene Shifting
6. Platform Staging

### I. HISTORY

**1. Greece.**—The earliest surviving complete Greek play, Aeschylus' *The Persians* (472 B.C.), was almost certainly presented in the bare earthen orchestra of the primitive Dionysian theatre. The action was appropriately set in the deserted countryside. When a wooden building, the *skene* (from which word are derived Latin *scaena* and English "scene"), was erected opposite the circle of spectators (*c.* 465 B.C.), its front wall began to influence the settings of the tragedies and comedies that followed. Each of its three (later five) doors was given a formal use—serving, for example, to indicate arrival from a distant place; this tradition continued far into the Renaissance. Later in the 5th century B.C. the wooden *skene* was replaced by stone. In the 4th century B.C. the *skene* acquired a long, narrow platform that elevated and separated the *dramatis personae* from the chorus in the orchestra.

Aristotle says that scene painting was first used for Sophocles; according to the Roman architect Vitruvius, it was for Aeschylus. It seems certain that painted panels were used on the front of the *skene*, perhaps in the same conventional style as Greek vase painting. The *periaktoi*, a three-sided device on which two scenes could be changed while the third was presented to the audience, was employed for quick scene changes. Vitruvius in *De architectura* distinguishes three types of settings—for tragic, comic, and satiric plays—during the Hellenistic period. He also describes a device called a *scaena ductile*, a moving scene on wheels, drawn onto the stage from the left.

In Greek theatres a subterranean passage below the orchestra emerged in "Charon's steps." There was also a variety of stage machines. The *eccyclema*, a movable platform much used in Euripides' plays to suggest interiors, may have been pivoted through, or pushed straight through, a stage door onto the stage. The *mechane*, a crane rigged at the top of the *skene*, was employed to lower gods from Olympus; this machine, as might be expected, was a source of humour for the Greek comic writers.

Greek plays usually began at sunrise, thus offering their dramatists all the effects of natural light; in Euripides' *Iphigenia in Aulis* the fading stars and the coming of dawn are both written into the action, which continues thereafter in full daylight.

**2. Rome.**—The *frons scaenae*, or facade of the building at the rear of the Roman stage, was gorgeously decorated with pillars, statues, and entablatures to a height of two or more stories; at

the top a roof projected over the stage. A curtain hid the stage at the beginning of a performance; it was dropped into a recess under the stage and raised once more at the end of the play. In later times the curtain came into use between acts, permitting changes of scene; it is not known how the temporary settings differed from the permanent architectural facade. As on the Greek stage, the *frons scaenae* represented a street, and interior scenes could not be shown; even banquet scenes had to be brought outdoors. The evidence suggests that the so-called architectural stage was the result of some measure of choice rather than circumstance, since scenery of considerable realism was available in the 1st century B.C., at the beginning of stone theatre building in Rome. Furthermore, by the period of decadence both the ballet (not performed in the theatre) and the arena had adopted scenery of specific locales, together with elaborately contrived properties; the theatre had not.

Roman stage design, like the action of the play, proceeded conventionally. The appearance of the stage and the costumes and movements of the actors were as formalized in their way as the moves on a chessboard. Nevertheless, stage properties—spears, torches, even a chariot and horses—were real objects. It is not likely that the playwright-directors of the Greek and Roman theatre discriminated between the conventional and illusory elements they employed. Indeed, not until the advent in modern times of Naturalism and Epic Theatre were stage people much concerned over that mixture of styles.

**3. China.**—The platform of the Chinese stage was originally set up in teahouses and palaces. In its present form it is almost square. A rear wall and two lacquered red or black columns downstage (nearest the audience) support the stage roof. The wall, covered with a silk-embroidered curtain, has two curtained openings: an entrance (right) and an exit (left). Musicians sit at one side of the stage. Property men not only set the stage in full view of the audience but are in attendance on the actors at all times; they even bring them stage properties, taking away the properties when the actors have finished with them. The use of properties is, as a rule, formalized; e.g., an actor may step up on and down from a chair to indicate that he has crossed a mountain. On the other hand, many of the properties are used quite literally.

For stage design in Japan (derived from Chinese practice), see KABUKI THEATRE; NŌ DRAMA.

**4. Middle Ages.**—In the Western world during the Middle Ages the church became the scene of the drama, revived after a long period of degeneration. Beginning in the 10th century the mystery play used the raised area of the altar to show the events of Easter and Christmas, erecting there a tomb or decorated manger. The stories of Christ's birth and passion were retold within a setting composed of religious sculpture and painting, coloured lights from stained-glass windows, music, and incense, with the addition of costume and spectacle. This liturgical "theatre" fused dramatic and scenic elements to achieve the synthesis advocated centuries later by Richard Wagner (q.v.; see also ART: *Concerts of Arts*).

As the size of the audiences increased, plays were transferred to the west door of the church and then outside church precincts. These plays featured a number of booths, or "mansions," each representing a locale of the story; e.g., a decorated Heaven (which might be in the upper part of a two-leveled wagon), or a Hell mouth belching smoke. The booths were simultaneously available to the action, with the players making appropriate entrances and exits. This type of staging was continued for miracle and morality plays and, in England, for the guild pageants.

Nor was machinery absent during the Middle Ages. An elaborate spectacle was staged about 1400 in the Church of S. Felice in Florence for the Annunciation. A "nosegay" of singing cherubs was suspended in a copper dome in the roof of the church, from which descended a copper globe, opening to reveal the angel. The *nuvole*, moving clouds which revealed personages in the tradition of the Greek *mechane*, seem also to have originated in the church in the 15th century, the mechanisms being masked by cotton wool. Fires, fountains, thunder, fireworks, and the like were popular effects in the passion plays.

**5. Renaissance.**—At the Italian courts theatres ranked high as an index of social and political prestige. Banquets, masked balls, and other festivities were enriched by neoclassic entertainments designed by leading artists. Roman comedies were revived and a number of playhouses were built on what were supposed to be classical models after the publication of Vitruvius' *De architectura* in 1511. The best known of these is the Teatro Olimpico (completed 1583) at Vicenza. Vincenzo Scamozzi's elaborate *frons scaenae* was pierced by doorways through which were visible (as through street gates) street scenes in forced perspective. Action took place in front of this scene.

The introduction of perspective (q.v.) was as momentous for scene design as was that of electric lighting later. The first recorded use of perspective on stage was for Ariosto's *Cassaria* at Ferrara in 1508. Its success laid the groundwork for a facsimile imitation of nature. A few years later Baldassare Peruzzi showed how painted perspective scenes could prove as effective as those with sets of solid wooden three-dimensional wings, recommended by Sebastiano Serlio. When Serlio's *Second Book of Architecture* appeared, in 1545, it contained designs in perspective for stock scenes of comic, tragic, and satiric plays. The choice of one of three settings may seem totally inadequate to a modern audience, but this arrangement based on Vitruvius was a real advance; for whereas the classic stage used a single, permanent facade with modifications, Serlio's stock sets fitted the whole stage setting to the type of play.

During this period the rediscovered *mechane* of the Greeks came into frequent use in the form of the *gloria*, or *paradiso*, a hoisting scaffold masked by cutout, painted clouds. The Renaissance stage also had trapdoors and machines, including devices for creating thunder and lightning. There were moving suns and moons, and even conflagrations, accomplished with a liberal use of aqua vitae. There was also a beginning of an aesthetics of stage lighting. About 1550 Leone de' Somi in his *Dialoghi in materia di rappresentazioni sceniche* (*Dialogues on Stage Affairs*) considered the problems of achieving natural-looking scenes of day and moonlight and was the first to counsel lighting from one side to give a plastic effect to the scene. The intensity of lights was controlled for mood and dramatic effect; e.g., comedies were well lighted, but at intimations of tragedy the lights were dimmed.

Another significant step in the direction of modern staging was the completion, in 1619, of the Teatro Farnese, at Parma—an elaborate theatre with a permanent proscenium, or decorative frame, forming an arch with a stage curtain in front of the scenery. (About 50 years earlier Francesco Salviati had introduced the proscenium frame as a temporary structure for performances at court.) The changing of scenery to suit different locales did not occur at once, however, emphasis being at first on atmosphere and spectacle. The falling of the proscenium curtain for scene changes between acts was not common in England until the mid-18th century, and until the late 19th century the convention of visible scene changing continued.

The first mode of shifting, as generally practised, was to remove the house fronts of the first scene, revealing those of a second scene behind them. As the front sets of Serlian houses were more or less three-dimensional, this offered some difficulties; the practical tendency, therefore, was to strip down the weight of these constructions, and this eventually resulted in two-dimensional wings and backdrops that could be peeled off like cards off a deck. By the beginning of the 17th century this arrangement had been completed by sky borders—hanging horizontal strips of blue cloth, six feet apart in depth, bridging the stage above the wings.

Many practical suggestions for making shifts were offered by Nicola Sabbatini in the *Pratica di fabricar scene e macchine ne' Teatri* (*Manual for Constructing Theatrical Scenes and Machines*; 1638), a complete manual on every aspect of making and operating theatre machinery, including many magical effects, such as devices for simulating waves on stage. His ideas included the use of the *periaktoi* and the running of wing flats in grooves (soaped for smoothness), used in England (though less popular on the continent) until the 19th century.

By the close of the 16th century the work of Italian scene designers was already celebrated throughout Europe. The English designer Inigo Jones visited Giulio Parigi when in Italy in 1613-14 and returned to a successful career designing court masques, his opening-and-shutting scenes and use of moving clouds being particularly admired.

In France the Hôtel de Bourgogne, a theatre that had almost a monopoly of tragedy in Paris until the mid-17th century, favoured the use of multiple settings (*décor simultané*), also derived from Italy. All the locales were on the stage together (as with the medieval mansions). The plays of Corneille, which usually observed the unities, helped replace this with a single decor. When Molière first went to the Petit-Bourbon (1658) he was obliged to adapt his plays to the type of setting used by the theatre's regular tenants, a *commedia dell'arte* troupe called the Comédie-Italienne. This setting, a permanent one that showed houses arranged around a town square, was traditional, by then, for comic action, but it was shortly to be replaced by the Baroque (see below).

The scenic resources of the public theatres of Madrid at the opening of the 17th century were limited; however, those of Lope de Vega's plays performed at court, the *comedias de ruido* or *de teatro*, were staged with more pomp and machinery in the Italian manner. The new theatre built in 1635 in the palace of Buen Retiro was equipped for spectacular productions, and Lope's successor Calderón was to write for the full Baroque stage.

**6. Baroque.**—The wings-and-backdrop setting characterized the Baroque, which in France continued the Italian tradition of scenic splendour but with greater mobility and ornateness. Wings were placed three or more on each side of the stage, parallel to each other and at a slight angle to the footlights, with the backdrop closing the rear; on a deep stage, with the floor raked toward the back, the whole gave a picture of a deep perspective—a street, a path through a park, a corridor in a prison, and so on. Spectacles were common. In spite of its use of perspective and of *trompe l'oeil* painting, the Baroque set was distinctly conventional. Its total effect was that of a flimsy architecture, a gracious, elaborately painted formal area; its formality was accentuated by the chandeliers that hung over the stage and shed their radiance impartially over a succession of locales that might even include a vista of a storm at sea. Action was usually carried out on the extensive forestage, since at least one-third of the audience could not see to the depth of the main stage. The actors, however, gradually retreated into the scene, the forestage shrinking until the 19th century "picture stage" was complete.

From the Teatro Novissimo of Giacomo Torelli (1608-78) in Venice came the theatre machinery used throughout Europe during the next two centuries. This machinery included the revolving stage and most of the other devices known to the modern theatre. Most famous was a method of quick scene changing: wings ascended from the basement through slits in the stage on battens or ladders called masts, the whole movement being controlled by a drum belowstage.

After the middle of the 17th century this system of machinery was gradually adopted in France. Corneille wrote *Andromède*, staged in 1650 at the Petit-Bourbon, to show off the latest Italian machinery of Torelli, brought to Paris in 1645 at the command of Louis XIV. When the Petit-Bourbon closed in 1660, Molière's troupe transferred to the Palais-Royal (built in 1641 by Richelieu), which had ample scenery space. This theatre was re-equipped in 1671 with the latest machinery for the staging of *Psyché* by Molière. By 1660 the Théâtre du Marais was beginning to specialize in so-called machinery plays. The new Comédie Française (1689), into which the amalgamated comedy troupes moved, was well equipped with machinery.

Outdoor theatres of an intimate type, with living hedges for wings, were a charming variation of 18th-century theatre. (The garden theatre at Drottningholm, Swed., is a fine example.) These were the work of landscape gardeners. The indoor Baroque settings, however, were planned by professional scenic artists who were individually famous. The most outstanding of these were the Italians, who practised their art throughout Europe. Chief among them were Bernardo Buontalenti (1536-1608), G. L. Ber-

nini (1598-1680), Lodovico Burnacini (1636-1707), Giambattista Piranesi (1720-78), and members of the Galli da Bibiena family (three prolific generations, from the mid-17th century to nearly the close of the 18th) and of the Galliari family (throughout the 18th century). (For a detailed exemplification of the Italian influence, see BIBIENA, GALLI DA.) Their legacy is evident in the contemporary French theatre, which relies to a noticeable degree on painted scenery. It is seen also on most of the world's operatic stages; in ballet, where "painty" settings had a renaissance in the work of pre-Soviet Russian designers (Léon Bakst, Nicholas Roerich, Alexandre Benois, Nathalie Gontcharova, Mikhail Larionov, and Serge Soudeikine); and in backdrops by French artists of the rank of Picasso, Léger, Matisse, and Dufy. Baroque design in the theatre was so distinctive, so remarkably integrated, that the following two centuries witnessed a continuing accommodation to it along with a struggle against its authority.

**7. Popular Theatre.**—Side by side with the court theatres of the Renaissance and the Baroque there existed a popular theatre known in Italy as the *commedia dell'arte*, or professional comedy. This was a theatre of wandering actors, hardly more than gypsies in status, who performed their coarse, comic improvisations at fairs and in marketplaces. Their stage, a bare platform laid over trestles or barrels and backed by a shabby painted curtain, was the same as that used for the medieval farces known as interludes, the Hanswurst comic plays of Germany, and the student dramas of Bohemia. (The mobile popular theatre, the *carpa*, of Mexico is a living example.) Sometimes these itinerant companies were able to use enclosed innyards, where they could erect their platform at one end. Such were the pre-Elizabethan theatres of England and the very similar *corral* theatres of 16th-century Spain. The stages remained platforms but with an awning to shelter them from the weather. For the revival of the platform stage in the 20th century, see *Scene Shifting*, below.

The stage of the Globe, the theatre in which the plays of Shakespeare were performed from 1599, ran deeply into the audience. At the back was a small, curtained inner stage in which scenes could be "discovered." Above this was a balcony, and above this a musicians' gallery—an arrangement that offered a choice of acting levels. In the attic were winches by which heavy properties, such as a throne, could be lowered to the stage floor. Traps were available, along with a variety of effects, including fireworks. Tables, chairs, and other furniture were moved by stagehands, visible to the audience, or as part of stage business by actors. On-stage killings were commonplace in Elizabethan drama, and provision had to be made for removing dead bodies from the curtainless main stage by the actors, plausibly motivated. (Two well-known examples occur in *Hamlet*: the prince "lugs the guts" of Polonius into a "neighbour room" and is himself carried out, near the close of the play, on the shields of Fortinbras' troops.) As in the Japanese Nō theatre, isolated scenic elements helped to indicate locale: two or three small trees to suggest a forest; rope rigging, stretched from the balcony or gallery to the stage floor, to suggest the deck of a ship. These tokens of locale, however, remained entirely subordinate to the free use of stage space; the dramatist himself identified the environment of a scene by allusions to it in the dialogue. Stage lighting was equally naïve. Since performances began at 2 p.m. in this roofless theatre, daylight was the normal illumination and lighted candles or torches were only part of the stage business. The Shakespearean stage, however, for all its apparent naïveté, had a remarkable fluidity of movement, which explains how *Antony and Cleopatra* (1607), with its 38 scenes, could have been performed without stage waits. Much of Shakespeare's vigour and pace were lost when his plays were presented later on, with the painted drops and cumbersome interiors fashionable until the end of the 19th century.

Public performances of Shakespeare, however, must be distinguished from private and court performances where the multiple setting (as employed at the Hôtel de Bourgogne) and signboards indicating locations may have been used. Elaborately staged court masques had always been a tradition separate from drama, and an attempt to unite the two arts early in the 17th century led in England to bitterness between the playwright Ben Jonson and

Inigo Jones. Plays were not wed to the scenic tradition in England until the Restoration, with the opening of indoor public theatres.

An English amateur group, the Elizabethan Stage Society, under the direction of William Poel, between 1895 and 1905 undertook performances in the manner of the Globe Theatre. Subsequently, Shakespearean plays lent themselves to endless scenic experiment, but almost always with a dominant feeling for the movement of the actor in space.

**8. Romanticism and the 19th Century.**—In the mid-18th century Baroque formality was being challenged in the theatres of France, England, and Germany. The greatly expanded middle-class audience influenced not only the choice of plays and the manner of acting but the setting as well. By the mid-19th century this had resulted in both the elaboration of the Baroque stage and its decay. While retaining wings-and-backdrop, the Romantic stage abandoned the formalism of the Baroque. Architectural perspective was replaced by a neo-Gothic sentimentalization of nature: moonlit mountains, exotic, palm-fringed landscapes, weeping willows over riverbanks were familiar scenes. Wing scenery was pushed to the extreme sides of the stage, which was now dominated by the backdrop; the forestage practically disappeared.

With painted Romantic scenery came a growing scientific awareness, but this was often pedantic and "antiquarian." In 1823 J. R. Planché designed the costumes for Charles Kemble's production of Shakespeare's *King John* on the basis of painstaking historical research, and every Shakespearean production thereafter took academic advice on the historic accuracy of its sets and costumes.

Gas lighting, though concealed from the spectators, now revealed every detail of the elaborate settings. Leading scene designers of the period included Philippe Jacques de Louthembourg, who took charge of the sets for David Garrick's productions; he used not only the type of cutout drops made famous by the Bibiena family but also transparent scenery for magical effects, and he introduced the act drop—a painted drop that conceals a change of set going on behind it while action continues on the narrow strip of forestage in front. He and such scenic artists as William Capon (1757–1827), who designed sets for J. P. Kemble, and Goethe's designer, Karl Friedrich Schinkel (1781–1841), bathed the whole stage in an "atmosphere" of picturesque illusion.

By the 1850s the wing system had altered: interiors showed side walls and a back wall, with doors and windows, as in the production in London of Dion Boucicault's *London Assurance* (1841)—but the doors and windows were of framed and painted canvas, as a rule, and even some of the furniture was painted on the walls in *trompe l'oeil* style. In the United States, at least, this type of shoddy painted scenery endured until the ascendancy, about 1900, of the director David Belasco (*q.v.*). Without really abolishing the Baroque form, the Romantic set had deprived it of meaning. The conventional splendour of court theatricals had become the outer dress of psychological, middle-class drama.

Reform in scene design began in the 1870s with the work of the director-designer George II, duke of Saxe-Meiningen, a small German principality. He turned away from the two-dimensional setting and the bare stage floor and required that the setting be related to the actor architectonically; he broke up the stage floor into dramatic levels and utilized stage lighting both as a realistic and a dramatic element in production. Characteristically, Meiningen did not merely design backgrounds: before going into rehearsal he drew, in pen and ink, whole scenes showing the actors in the proposed settings.

**9. Naturalism.**—The Meiningen troupe's methods had their effect upon the younger stage people of Europe and particularly upon André Antoine, a Parisian amateur director, who was also impressed by Émile Zola's statement that "the experimental and scientific spirit of the century will enter the domain of drama." Stage Naturalism can be dated to the staging of Zola's short play *Jacques Damour* in 1887 in Paris by a newly organized group of amateurs, the Théâtre Libre, under Antoine's direction. The movement toward transposing to the stage "life as it is" showed itself not only in the nature of the play but also in the setting of a back room of a shop: its furniture was imported from the dining

room of Antoine's mother. For *Les Bouchers* (1886) real carcasses of beef were hung on the stage. The proscenium opening now became the imaginary fourth wall of interiors that were facsimile reproductions of real environments.

The new style took firm root at the Moscow Art Theatre (*q.v.*), founded by Konstantin Stanislavski and Vladimir Nemirovich-Danchenko in 1897. As directed by Stanislavski the plays of Chekhov, Turgenev, Tolstoi, and Gorki became masterpieces of Naturalism. Stanislavski's directorial notebook for his production of Chekhov's *The Seagull* in 1898 contains ground plans of the entire Sorin estate: the park of birch trees, the house with its veranda, the lawn, the path, the lake, the little stream with its wooden bridges—for he wished to steep himself in a complete illusion of the estate. Within a decade the so-called Free Theatre movement had conquered the Western world. Ibsen played a part in this, his *Gengangere* (*Ghosts*) being selected for the opening performance of the Freie Bühne (1889) under Otto Brahm in Berlin and the Independent Theatre (1891) in London organized by J. T. Grein; and in 1890 it was performed at the Théâtre Libre. August Strindberg, too, wrote for the Naturalistic stage, only to revolt against it in the last two decades of his life. In New York the movement was sponsored by David Belasco; by the beginning of World War I, "Belascoism" had triumphed in the United States theatre.

**10. Symbolism.**—In Paris reaction against Naturalism came swiftly. In 1891 Paul Fort organized the Théâtre d'Art and urged the spectator to "abandon himself completely to the poet" and to see "visions terrible and charming, lands of deception into which none but he [the poet] can penetrate." The Symbolist opponents of Naturalism had no use for "the carcass of reality" or for "the prose theatre": they wished to capture not a facsimile of life but its essence. For their settings they had the assistance of painters like Pierre Bonnard and Odilon Redon; but it was Fritz Erler, Symbolist designer for the Munich Künstlertheater, who gave full expression, scenically, to the new point of view. His settings for *Faust* in 1908 were characterized by shafts of light, pools of shadow, light joyous or sorrowful, and colours calculated to affect the emotions.

The U.S. producer and drama critic Kenneth Macgowan in 1921 condensed the scenic program of the Symbolists into four main principles: simplification of effect and means; a proper relationship of actors to background; suggestion, as when a single candlestick served to give the whole quality of the Baroque period for *La Tosca*; and synthesis, "a complex and rhythmic fusion of setting, lights, actors, and play."

In electric lighting, which had replaced gas on the world's stages by 1900, the Symbolists found an invaluable ally. It brought out the planes and accentuations of the setting, created a cubic volume of stage space, and in conjunction with the plaster cyclorama, a curved rear wall that reflected light without shadows, gave the effect of infinite vistas. To the Swiss Adolphe Appia (*q.v.*) the modern theatre is indebted for both theory and practice in handling this new medium. Designing for Richard Wagner in Germany, he showed in sketches, models, and light plots how Wagner's idea of "the projection of music into visible scenic form" could be carried out onstage. The result was the plastic setting, a sculptured or architectonic structure shaped to the movement of the actors. It proved especially valuable for Shakespearean and other many-scened plays, in which a combination of steps, platforms, and ramps became a generalized stage on which the light played in a continuously changing pattern.

The Symbolist technique created a corps of brilliant stage designers and directors the world over. Yet Symbolism, with its search for the essence of locale, did not prove altogether satisfying to its adherents. It was more selective, more colourful, more poetic than Naturalism; but it could be criticized as being merely Naturalism purified. Just as Antoine and Stanislavski felt the need to go beyond Naturalism into Symbolist experiment, so the Symbolist designers and directors were inclined to abandon the picture stage and to return to the older, direct form of theatre. Their thinking—called, without any derogatory connotation, Theatricalism—was summed up by the U.S. designer Norman Bel

Geddes (*q.v.*) when he said, "There is no more reason or logic in asking an audience to look at a play through a proscenium arch than there would be in asking them to watch a prize fight through one."

**11. Theatricalism.**—Theatricalism attracted designers like Edward Gordon Craig (*q.v.*) in England and Robert Edmond Jones (*q.v.*), Lee Simonson, and Geddes in the U.S. It appealed to directors like Max Reinhardt (*q.v.*) and Leopold Jessner in Germany, Jacques Copeau, Louis Jouvet (*qq.v.*), A. M. Lugné-Poë, Charles Dullin, Gaston Baty, and Georges Pitoëff in France, and Vsevolod Meyerhold (*q.v.*), Aleksandr Tairov, and Evgheny Vakhtangov in Russia. In their view, to turn one's back on Naturalism—even on the selective Naturalism of the Symbolists—was to draw inspiration from the spirit of the theatre itself. The picture-frame stage called for passivity of response in audiences and their separation from the actors, lest the spell of illusion be broken. Wagner understood this so well that when his Bayreuth opera house was opened in 1876 it contained a deep orchestra pit (a "mystic abyss") and not one but two prosceniums intervening between stage and public. The Theatricalists, on the contrary, favoured a platform projecting into the audience to put the actor in the same room as the spectator, in direct alert contact. They accepted the obvious truth that the playgoers were in a theatre and that actors were on a stage, carrying out dramatic action with the help of settings that were obviously scenic constructions illuminated by stage spotlights; and they believed, further, that the abolition of barriers between actors and audience was reestablishing full dramatic communication between them.

This dramatized the difference between the Naturalist-Symbolist technique of illusion and the method of convention, which was the immemorial usage of theatre. With the Theatricalists the contrast was unmistakable, though it was never absolute. Thus in his Symbolist settings for Shaw's *Back to Methuselah* in 1922 for the New York Theatre Guild, Simonson made use of projected back-grounds that were a palpable artifice. Another U.S. designer, Jo Mielziner, frequently pushed beyond the boundaries of Symbolism to Theatricalism, especially in his use of transparencies; *e.g.*, in his designs for Arthur Miller's *Death of a Salesman* in 1949, in which parts of a house were rendered transparent as if by X-ray.

In musical plays and ballet, partly because of the exigencies of shifting and partly because a certain extravagance of style is traditionally expected, the Theatricalist tendency was much stronger than in drama: *Oklahoma!* as designed by Lemuel Ayers in 1943, or *My Fair Lady* in the settings by Oliver Smith in 1956, were outstanding examples. Theatricalism in drama was especially evident in the many-scened play, which almost always demands an arrangement that is basically abstract, even though each component scene appears as a plausible illusion; *e.g.*, Mordecai Gorelik's designs for the New York Group Theatre's 1933 production of Sidney Kingsley's *Men in White*, where the play's seven scenes, each a room in a hospital, consisted only of furniture or screens that appeared inside an architectural frame.

Akin to Theatricalism was the technique of stylization, which took one aspect of a locale as a convention for its whole quality; *e.g.*, the use by Simonson of Japanese screens as backgrounds throughout John Masefield's *The Faithful* in 1919. For *Macbeth* in 1921 Jones used, throughout, a group of Gothic arches that seemed to advance in military formation during Macbeth's rising career, but with the tyrant's later decline in fortunes a single arch remained leaning awry. This, however, was mild compared with the more extreme forms—Expressionism, Dadaism, Surrealism—that pushed Symbolism to its farthest limits.

Expressionism, mostly a German phenomenon (though foreshadowed by Strindberg in Stockholm at the end of the 19th century) originated in 1910 at the Sturmbühne in Berlin and reached its full development during and after World War I. It took a subjective, often hysterical view of environment. For example, Max Slevogt's design for Mozart's *Don Giovanni* at Dresden in 1924 twisted the palace out of shape; Vakhtangov presented S. Ansky's *The Dybbuk* in 1922 in a quasi-Cubist style that gave additional eeriness to the tale of demoniac possession; and at the Kamerny Theatre, Moscow, Aleksandr Tairov presented Racine's

*Phèdre* in 1922 and Eugene O'Neill's *Desire Under the Elms* in 1926 in a style that was Cubist even to the makeup of the actors.

G. Apollinaire's *Les Mamelles de Tirésias*, staged in Paris in 1917, was the ancestor of an assortment of plays that challenged not only Naturalism but reality; its staging was inspired by Dadaism (*q.v.*), the more destructive precursor of Surrealism (*q.v.*). With its ideological program of the liberation of the unconscious (even at the expense of apparent disintegration) as an irrational creative force, Surrealism inspired Salvador Dalí's backdrop for the 1939 performance at Monte Carlo of the ballet *Bacchanale*, which showed a gigantic swan with a ruined pediment lodged in its neck; and his 1949 set for the scene of the dance of the seven veils in Oscar Wilde's *Salome* at Covent Garden showed a neo-Gothic pavilion under a scarred and frightening moon and with a great peacock's tail for background. Less grotesque was Pavel Tchelitchew's set for Jean Giraudoux's *Ondine* (1939), where the fisherman's hut turned transparent to reveal a structure of fishes' bones. Cryptic in such plays as Ionesco's *The Chairs* (1947), Kafka's *The Trial* (1949), and Samuel Beckett's *Waiting for Godot* (1952), Surrealism lent itself to communicable satire. For example, Christian Bérard's set for Giraudoux's *La Folle de Chaillot* (1945) included a house front with nothing behind it; the V and W Theatre's presentation in Prague of *Heaven and Earth* (1936) parodied the Baroque style; and Kjeld Abell's designs for his own play *Melodien, den blev væk* (*The Melody That Got Lost*), produced in Copenhagen in 1935, cynically pointed up with magic lantern slides the dreariness of lower-middle-class life.

A thoroughgoing Theatricalism includes a return to platform staging—or at least to its psychology, since Theatricalists often perforce had to do their work on picture stages. Beginning at Munich in 1906, Max Reinhardt proceeded to re-create, in vast spectacles, some of the platform classics of the earlier eras of theatre. For *Sumurun* (1912), *The Miracle* (1911), and *Danton's Death* (1916) action took place partly on the stage and partly in the centre of the orchestra, with the actors coming to the stage through the aisles of the theatre. The grandiose quality of these productions was fully realized, beginning in 1919, in the arena of the Grosses Schauspielhaus, a reconstructed circus building in Berlin. In his nonarena presentations, Reinhardt at times made use of a huge revolving stage that turned in full view of the audience, the actors moving at the same time from one section of the turning stage to another. For *Othello*, in 1910, five major scenes were preset as a miniature Venice complete with canals and bridges.

In Petrograd, Vsevolod Meyerhold removed the proscenium and front curtain of the Aleksandrinski Theatre and presented Molière's *Don Juan* in 1910 with little Negro servants moving properties and ringing tiny silver bells to engage the attention of the audience. Less spectacularly, Copeau, at the intimate playhouse of the Vieux-Colombier, Paris, erected a permanent scenic facade on his curtainless stage, varying its details for each of his productions.

The greater vitality of Theatricalism resulted sometimes in productions of genius, sometimes in productions that were displays of dazzling mediocrity. Having carried out its mission of smashing the atmospheric stage picture, the movement could not merely go on reiterating that theatre must be theatre.

**12. Socialist Realism.**—To the dismay of many of the older people of the theatre, a new philosophy appeared in the Soviet Union proclaiming the theatre a weapon in the class war. After 1934 the Soviet ideal in the theatre was officially declared to be Socialist Realism, by which was meant stage productions realistic in orientation and socialist in political viewpoint. Meyerhold embraced this view, "seizing his audience by its lapels" and turning direct staging into a political virtue. Condemning the picture stage as bourgeois, Meyerhold tore out not only the front curtain of the stage but its sky drop as well, exposing the stage to its back wall and gridiron. His version of Gogol's *Revizor* (*The Inspector General*) in 1926, with its semicircle of 15 polished mahogany doors and raked platforms, was his outstanding achievement. Of great technical interest is his period of Constructivism: his production of Émile Verhaeren's *Les Aubes* (*Dawns*) in 1921

used, in utter negation of facsimile, structures resembling builders' scaffolding whose purpose was not to imitate any interior or exterior but to give the actors new and dramatic ways of moving about.

Meyerhold's successors were mindful of the values of Constructivism but rejected nonrepresentational settings for recognizable locales. Among Soviet directors most indebted to Meyerhold was Nikolai Okhlopkov, who produced "in the round" at the Realistic Theatre, Moscow, from 1932 to 1936. In the era of Stalinist reaction, Okhlopkov's arena productions became less popular in the U.S.S.R., but they inspired a major trend in the noncommercial playhouses of the United States.

Besides emphasizing directness and exploring stage space, Soviet scenic art established the principles known as machine-for-theatre and environment-in-motion. For Soviet designers, as for the Naturalists, the setting represented an environment, not mere decorative background: it affected human beings and was affected by them. Technically, the settings were considered to be mechanisms serving the actors and were capable of movement. The English stage historian Huntley Carter compared Soviet settings, like those by Isaak Rabinovich for Aristophanes' *Lysistrata*, in 1923, to "a scientific toy which can be taken to pieces and put together in different forms." Designed for the Moscow Musical Theatre, a group of colonnades was used in various combinations to form the streets, citadel, and gates of Athens. For the Kamerny Theatre production of Vsevolod Vishnevsky's *The Optimistic Tragedy* in 1933, the designer Vadim F. Rindin employed a raked turntable containing a pit and working on an eccentric pivot so that, with minor changes, it served equally as a battleship, a shell crater, trenches, or a prison camp.

The political aspect of Soviet theatre is illustrated by Nikolai Akimov's production of *Hamlet* at the Vakhtangov Theatre in 1932. By surrounding Hamlet with books and scientific instruments while exaggerating the rude military architecture of Elsinore, he emphasized the contrast between the feudal court and Hamlet himself, a man of the Renaissance. This influencing of the spectator by emotional partisanship is, of course, common also to the bourgeois theatre, though the morals drawn differ.

**13. Epic Theatre.**—Problem plays staged with a medley of nonillusory ("living newspaper") techniques comprised the Epic Drama, which was almost the personal handiwork of the director Erwin Piscator and the playwright-director Bertolt Brecht (*q.v.*). Piscator inaugurated, with his staging of Alfons Paquet's *Fahnen* (*Flags*) in Berlin in 1924, the use of film sequences on stage. In 1927 in Piscator's *Die Abenteuer des braven Soldaten Schweik* (*The Good Soldier Schweik*) fragments of scenery, as well as life-size cutout cartoons, traveled across the stage on a double treadmill while an animated antiwar cartoon unfolded on a screen behind the actors. Leo Lania's *Competition* in 1928 showed oil derricks actually being erected on stage. In the same year and also in Berlin, Brecht's *Die Dreigroschenoper* (*The Threepenny Opera*) had a pipe organ outlined in electric lights as a permanent background, along with free-standing pieces of scenery that included iron-barred prison cages and a long stairway on casters. Brecht did not resort to films on stage but did use projection screens showing explanatory titles and illustrations, usually one on either side of the stage or above the actors' heads. Half-curtains strung on wires across the front of the stage screened the scene changes but otherwise left the proscenium open. Brecht's most impressive drama, *Mutter Courage und ihre Kinder* (*Mother Courage and Her Children*), as staged by Brecht and Erich Engel at the Deutsches Theater in Berlin in 1949, also had half-curtains and projected titles: The production contained no settings in the ordinary sense, only stage properties; even the two peasant huts had the quality of "props." The main feature was Mother Courage's market wagon, which rolled from country to country and from year to year, maintaining its place against the movement of a revolving stage. The many locales were indicated by means of names woven out of tree branches and let down from the flies. The lighting, otherwise completely uncoloured, changed to a golden illumination for the song numbers.

The stage methods of Brecht and Piscator aroused a lively in-

terest in Germany before both men went into exile in the U.S. for the duration of World War II. The Berliner Ensemble, organized in East Berlin on Brecht's return and run by his wife, Helene Weigel, established a reputation as the most advanced of the world's producing companies. In part it owed this reputation to the talent of its scene designers, among them Caspar Neher, Theo Otto, and Karl von Appen.

The scenic innovations of Epic Theatre were part of a conception of staging larger than that of its contemporaries. In part its staging method was the result of inadequate playscripts: both the films and the still projections were intended to expand the material of scripts written by "psychological" dramatists who were unaccustomed to a larger scope in playwriting. Neither Brecht nor Piscator felt that his particular trademarks in production were more than the crude beginning of a new, classic technique in the theatre. Still the Epic scenic methods were already carrying out Brecht's principle of alienation (a term perhaps better translated as "distancing" or "cooling"). Brecht's purpose was to hold the dramatic story at arm's length, to "cool it off," in order to make his audiences more reflective and critical, to keep them from being swept away by an overemotional empathy. His use of lettered comment or projected titles was one means of putting a brake on audience excitement. Brecht's theory was thus directly opposed to Wagner's.

The Epic setting was so strictly functional that it could not be distinguished from an organized group of large stage properties. It was *sachlich* (finite, materialistic). It banished all scenic "atmosphere" from the stage: locales were represented in documentary form, by means of properties, by such fragments of reproduced environment as were necessary for the action, or by "reports" (*i.e.*, photo-murals or framed paintings hung behind or above the actors). Working in an "inductive" rather than "deductive" manner, the designer supplied the actors with whatever was required for their work—furniture and other properties, doors and windows (sometimes without surrounding walls), lighting to make the actors clearly visible. The lighting did not attempt to simulate natural effects but functioned obviously as stage illumination. In contrast to Wagner's principle of synthesis, Brecht called for autonomy for each of the stage elements, demanding that they be used in the precise, deliberate manner of a lecture-demonstration. At the same time this did not relieve the Epic designer of the need for making his materials and their composition as beautiful as they were functional.

Conservative Marxist critics were as dubious as many Western commentators about the merits of Epic staging. However, the postwar presentations of the Berliner Ensemble and Piscator's resumed work in Hamburg and West Berlin made a deep impression. Epic was so totally conventional that, for the first time in the history of theatre, it put an end to the dichotomy between conventional and illusionary staging. At the same time it was not unprecedented; it shared many of the tenets of Theatricalism and was strongly influenced by Oriental staging. The most striking feature of Epic Theatre was its scientific bent, which opened a whole new field of scenic invention.

## II. CONTEMPORARY STAGE DESIGN

**1. Stage Equipment.**—Since most professional theatres now in use were built before 1940, their stages continue to appear as a gilded frame enclosing an animated, lighted picture. The stage area of these playhouses has a base of 70 × 35 ft. or more in width and depth, and a height of 70 ft. or more. The proscenium opening is roughly 35–45 ft. wide and about 30 ft. high. The proscenium width can be decreased by means of tormentors (framed vertical panels on either side), and its height can be reduced to a normal working dimension of about 14 ft. by means of the lower edge of the act curtain and of a teaser, or cloth border, hung overhead. The stage set (the scenery as a whole) occupies an area approximately 40 ft. wide, 25 ft. deep, and, if the backdrop or cyclorama, is considered, perhaps 30 ft. high. The stage floor outside the set accommodates stored scenery and properties, accessory switchboards, etc. Additional scenery is flown (hoisted) out of sight between the top of the setting and the gridiron next

FIG. 1.—PLAN OF A TYPICAL EARLY-20TH-CENTURY STAGE, 52 FT. WIDE AND 28 FT. DEEP WITH A PROSCENIUM OPENING OF 28 FT.

to the ceiling of the stage house. In older theatres the rear wall of the stage is equipped with pulleys and scaffolding for the use of scene painters.

From the gridiron, or series of parallel steel girders, ropes descend to wooden or steel-pipe battens to which drops, or parts of built settings, can be attached. The fly gallery, or fly floor, part way up one of the side walls of the stage, has a pinrail where the lines (rigging) are tied; the gallery also provides standing room for stagehands (flymen). The stage sometimes contains, closer to the proscenium, a lower and smaller balcony where the electrician operates his main switchboard.

Normally the centre of the acting area is supplied with at least one trapdoor; often the entire stage floor is made up of trapdoors. The floor is of soft pine boards to accommodate the screws that hold down the ends of stage braces. The braces have prongs that fit into cleats in back of the scenery flats (panels of painted cloth on wooden frames), which can thus be quickly placed and then supported upright on the stage.

The lighting units have swivel joints and are clamped to the steel-pipe battens or to vertical steel pipes. A large number of these units hang on the first pipe batten just behind the proscenium and above the set. Additional projectors, spotlights, strip-lights, and floor lights flank the set on movable stands called boomerangs, or are scattered at strategic points, including several places in the auditorium. For big musicals the lighting instruments may be counted in hundreds.

A decorative house curtain, or act curtain, closes the proscenium opening; in front of it, likewise filling the opening, hangs the safety (or fire) curtain, formerly built of sheet iron but now generally woven of asbestos. The curtains, like drops, rise or descend in one piece. The stage roof above the gridiron has a large glass skylight which can be opened swiftly to allow the escape of smoke in case of fire onstage.

In theatres built after World War I there were some noticeable changes in the appearance and operation of the stage. A system of iron counterweights and steel cables began to take the place of sandbags and rope rigging; in many new theatres the counterweight system is now handled electrically. The formal, inherited arrangement of footlights combined with borderlights (strips of lights directly over the set) gave way to a more elaborate and flexible system of light sources located on every conceivable perch around the set and even in hidden crevices in the set itself. The conspicuous footlights (almost a metaphor for theatre) were sunk discreetly into the floor of the stage or removed altogether. In a number of playhouses the cloth cyclorama was replaced by a plaster dome, consisting of a concave quarter-sphere of slightly roughened plaster, which gives a much superior illusion of sky or of unlimited space. Revolving stages of the type used in Japan, where they were worked by a hand-operated windlass under the stage, became a feature of many new Western theatres. Electrically operated by remote control, they could not only turn but could be raised or lowered above or below the stage level. It even became possible to load huge operatic sets on platforms in

the stage basement, sending them up, at the touch of a button, to replace one another onstage.

In more recent years there has been an accelerated movement away from picture staging and the so-called fourth wall. Instead of trying to reproduce "life itself" onstage, the tendency has been toward a straightforward acceptance that the stage is an artificial medium subject to its own laws of artistry. This has resulted in a shift of emphasis from the proscenium to the stage platform. Thus, on the "open stage" (as exemplified in the Vivian Beaumont Theatre, New York), while the proscenium may remain, it is no longer gorgeously decorated but merges into the side walls of the auditorium; it may be supplemented by smaller side stages and may be capable of moving electrically to widen or reduce the size of the main stage opening. As in the pre-19th century theatres, the forestage, or stage apron, thrusts into the audience, replacing the orchestra pit. In most theatres built since World War II, the enlarged forestage is a separate elevator unit, operated electrically. An even more radical departure from late Victorian and Edwardian tradition is the arena stage, surrounded on three (sometimes four) sides by the audience. In the United States the arena stage is often found as an experimental adjunct to the main stage in university and community theatres.

Innovations have continued in the system of stage lighting (see further STAGE LIGHTING). Sound effects have been electrified, and, in the form of recordings on magnetic tape, issue from sound-mixing tables, either backstage or from the electrician's booth at the back of the auditorium, being conveyed from there by means of amplifiers to various parts of the stage or of the house. An entire library of taped sound effects is available. During rehearsals the director, dance director, and scene designer communicate with backstage by "intercom." The stage manager can call actors from their dressing rooms by means of a buzzer and may even see them and the stagehands by closed-circuit television.

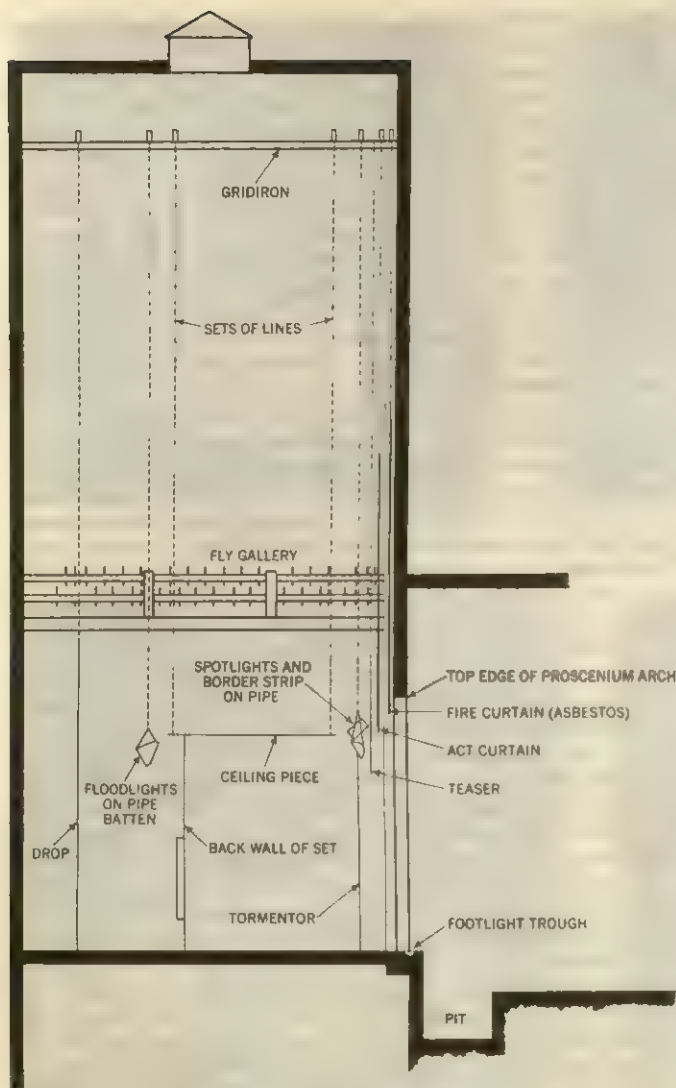

In addition to modern scientific devices, the stage may make use of special effects, many of them centuries old. They include shaded mirrors for the creation of phantoms; cables and harnesses to enable supernatural beings to fly through the air; breakaways of various kinds, including bottles made of wax, chairs and tables with legs sawed off and hinged back on, or stairs whose risers flatten out, forming a chute. There is lycopodium powder for sudden flames, and confetti for snow; there are plumbing and troughs for rain, fan-fluttered ribbons for torches and open fires.

Although mechanization and automation have found widespread use onstage and will in all likelihood continue to do so, their value in the service of drama is still contested in some quarters. Such gifted directors as Erwin Piscator have not hesitated to call for the installation of stages as superbly functional as modern factories. An opposing school of thought insists that the theatre was better off with less machinery and more imagination; and, that in practice, elaborate machinery, such as revolving and elevator stages, often lies neglected. The answer to this question may eventually be determined by the types of plays that are written and the demands made by dramatists on the stage technicians.

**2. Principles of Design.**—Design for the stage is a specialized art with its own laws. It is not an illustration of the locale of a playscript but is intended for the use of actors and is itself an element of the play's action. The designer must therefore be aware of the way in which the setting is related to the director's interpretation of the play. Factual documentation of history and geography, as in the Naturalistic theatre, is not enough. The designer's sets must express the underlying dramatic quality, which may differ from their ostensible appearance. This kind of analysis is called pointing up the theme; the stage director and the designer must agree about it and about the blocking (the charting of the actors' movements).

As a visual art, scene design obeys the laws of pictorial composition (the picture stage), of architecture and interior decoration (Naturalism), of sculpture (the plastic stage), and of engineering (Constructivism). At least two additional requirements are specific to scene design: the first is the law of sight lines—i.e., keeping the action and at least the significant parts of the

FIG. 2.—VERTICAL SECTION (SIDE VIEW) OF A TYPICAL EARLY-20TH-CENTURY STAGE

set within the audience's range of vision. Perfect viewing from all seats is rarely achieved, but the designer must do his utmost to increase visibility from all parts of the house, even at the cost of some distortion. The second specific law is economy of construction, shifting, storage, and transportation. The sets have to be put together and taken apart easily and quickly. In the United States professional scenery is not built in sections wider than 5 ft. 9 in., since a freightcar door is 6 ft. high.

**3. Working Out the Design.**—The designer and the director discuss the designer's rough sketches and ground plans. Agreement being reached, the designer makes finished sketches and a scale model (commonly  $\frac{1}{2}$  in. to the foot). Ordinarily the sketches are in water colour and the models in unpainted cardboard. When every aspect of the model has been approved, the designer or his assistant begins to draft the working drawings of the show. These include a dimensioned ground plan, front elevation, section, and a hanging chart showing where drops, curtains, cloth borders, and other "flown" pieces are to be hung from the gridiron. There are also detailed drawings of the more unusual or complicated sections of scenery and of all properties that are to be constructed. These drawings go to the carpenter, who prepares his own drawings from them. The designer (or, in some cases, a lighting expert) then prepares light charts in ground plan and section, showing what lighting instruments will be used, their location, and the areas they will illuminate. Scenery completed by the carpenter goes to the scene painter, to whom the designer has sent colour samples and scaled colour sketches. Supervision by the designer,

essential until the scenery has been finished and set up, includes finding the necessary furniture and other properties, or, if the required objects cannot be found, preparing working drawings for their manufacture.

**4. Scenery Construction.**—Scenery may be soft (unframed, as drops or curtains) or hard (framed, as flats, platforms, or built pieces). The scrim drop, made of fine-meshed netting, is much employed for magical effects, since it is opaque when lighted from the front but transparent when lighted from behind; the cutout drop is made partly of scrim and partly of canvas. The cyclorama, necessary for most outdoor scenes, hangs in a shallow curve behind the rest of the set and is illuminated to give the effect of sky. Black velour draperies, which absorb light, are commonly used for tormentors, teasers, and borders in order to mask off the edges of the set. All scenery, hard or soft, must be rendered flame-proof (though not necessarily fireproof).

In the 20th century there has been a marked tendency toward framed construction and heavy building, and a thin, flexible veneer called profile board is often used instead of canvas. The simplest framed unit is the rectangular flat used for sections of wall, for backings behind door openings, and (in a modified form) for ceilings. The ground row is an irregularly shaped flat resting on the stage floor and used most often to mask the lights that illuminate the lower part of the cyclorama. The built piece is a solid construction such as a window, door, or stairway. The standard stage platform, which folds together when not in use, is called a parallel. Parts of a set are joined by lashing with thin rope or by the use of hinges with removable pins. For storage, all pieces of heavy construction come apart from all flat pieces.

Most scene painting on flats is done with opaque water colours on the sized surface. Large drops and cycloramas are not sized but are painted with transparent dye colours. When careful painting of ornaments, human figures, or perspectives is required, the designer's sketch is transferred (as in mural painting) by dividing the design and the drop into marked-out squares and then copying outlines, one square at a time. Modern scene painters do little *trompe l'oeil* painting, but their work is nevertheless skilled: spattering and stippling are done with the brush, spraying with an air-brush; glazing, more customary in the case of oil paint, is used especially for woodwork.

**5. Scene Shifting.**—Shifting must be considered in the stage design. In shifting by hand, scene 1 may be removed and replaced by scene 2. For a faster arrangement, scene 2 may be placed behind and around scene 1, requiring only the removal of properties and certain flats from the first scene and the introduction of the properties of scene 2. (Obviously this arrangement will not do if the first set has to be larger than the second.) Movable platforms holding entire sets (including their furniture and properties) permit much faster scene changes and save labour, although their initial cost is high. A favoured platform method is the revolving platform, or turntable, occupying most of the stage area. Two sets are erected on it, back to back; scene 3 may be loaded while scene 2 is playing, and so on. If the locales are supposed to be adjacent in space they may be merged into a single composition filling the whole turntable, as was demonstrated by Reinhardt in his staging of *Othello* and *A Midsummer Night's Dream*. Sliding platforms, freewheeling on casters or moving on metal or fibre tracks, are also available for shifting.

Sets for arena theatres present some special difficulties. If the stage is entirely surrounded by the audience, large scenery must be excluded. The presence of doors and windows is implied by gestures; corners of rooms may be indicated by means of vertical strips of tape, wood, or metal. Furniture, however, must be arranged logically. It is virtually impossible to conceal the lighting units of the arena stage, nor is it really necessary to do so, since arena production is fundamentally Theatricalist. Still, light sources should be so placed that they do not glare into the eyes of the audience. On the arena stage, scenery must often be moved through the aisles of the theatre, and if quick shifts are desired they must be made in the dark. However, an arena-stage director, within the tradition of Theatricalism, can make adroit use of the property man, after the Chinese or Elizabethan manner. When

the stage is surrounded on only three sides, the wall side may be used for full-height settings, for practical entrances and exits, or for simple scene changes.

The semipermanent set, whether in the arena or on the traditional stage, has the minimum of things to shift. A classical instance was Simonson's arrangement for Eugene O'Neill's *Marco Millions* in 1928. A decorative neutral frame occupied the back wall and sides of the stage while nine scene changes from Venice to India, Syria, Persia, and China were accomplished by changing the scenic plugs that fitted into the three openings in the frame; there were also changes of properties, draperies, backdrops, and lighting. With the "simultaneous" set there is no scene shifting. The stage is divided into compartments and the lighting moves with the action from one area to another. An example was Robert Edmond Jones's setting for O'Neill's *Desire Under the Elms* in 1924, in which the lower and upper rooms of a New England farmhouse were visible, together with the front yard and gate.

Sometimes scene changes may take place in view of the audience as a deliberate part of the performance. Examples are the turntable scenes used by Reinhardt, the mobile elements in Brecht's plays, and the treadmills of Piscator. In the American theatre, shifts of this sort are likely to be found in musicals rather than in drama, but there have been numerous exceptions, as in the scene devised by Peter Larkin for John Patrick's *The Teahouse of the August Moon* in 1953, in which an entire teahouse was put together onstage in front of the audience. Displays of this sort are fully supported by Theatricalist technique, which looks upon the setting less as an atmospheric background for the actors than as a dramatic element in its own right. This functional aspect interests particularly the scene designers of the Soviet Union, who regard the stage set as "machine for theatre."

**6. Platform Staging.**—The stage platform in its most primitive shape (see above, *Popular Theatre*) took a new lease on life in the 20th century, with mobile acting companies using motor trucks for conveyance and temporary platforms for stages. Plays were thus brought into the remote areas of many countries, sometimes as adventurous student productions, as in the United States, sometimes as government-sponsored cultural or propaganda media, as in the Soviet Union, Fascist Italy, or Communist China. Often the platform of the truck itself was improvised as a stage, with scraps of settings to indicate locale. The *Schwankbühne* ("farce stage"), the early German version of the *commedia* platform, also found employment; Günther Weisenborn's drama *Tyl Eulenspiegel* (1949) in West Berlin and Carl Orff's comic opera *The Clever Woman* (1948) in East Berlin both placed *commedia* platforms boldly on the stage of the proscenium theatre, making good use of the flavour and vigour of this naïvely effective method.

**STAGE DIRECTING:** see ACTING, DIRECTION AND PRODUCTION.

**STAGE LIGHTING** is the youngest of the arts of the theatre. Playwriting, acting, music, theatre architecture, and scene design all have centuries of tradition behind them, but it is only since the development of electric light, i.e., since about 1880, that lighting has been capable of playing a major role on the stage. Lighting by open flame—torch, candle, oil lamp, or gas—provided illumination of a sort for the actors but allowed of little or no control. Electricity gave the theatre a source of light that was safe, convenient, flexible, and fully controllable.

The tendency of the 20th-century theatre toward scenic variety and flexibility, e.g., in the use of platforms and ramps as acting areas, would have been impossible without controlled lighting. Stereotyped sets consisting of flat walls, backdrops, and borders are disappearing, and creative lighting with architectural forms and drapery is taking their place. The designer now uses light as one of his major tools, and with it makes clearer, cleaner stage pictures than his predecessors ever achieved with tortured detail in paint, wood, and canvas. Thus, a column and a stained-glass window make the entire stage a cathedral; a corner of a facade, when lighted, becomes an entire building; and a single shaft of light into empty space illuminates anything from the fields before Troy to the interior of a crowded nightclub.

This article is concerned mainly with the technical aspects of stage lighting. For the aesthetic role of lighting in dramatic representation, see STAGE DESIGN. Information on particular types of lamps mentioned may be found in the article LIGHTING.

## HISTORY

**Early Lighting.**—Torches, lanterns, or candles have been carried onto the stage at all eras to indicate darkness. The Greeks occasionally used fires when their dramas continued after sunset, or to indicate night scenes. The Roman theatres may sometimes have given evening performances lighted by torches and oil lamps. When private theatrical performances began to be given in indoor halls, after dark, the problem was to provide light on the large scale needed to illuminate the entire hall, as much as to light the stage.

The first treatise describing artificial light as an integral part of stage presentation is that of Sebastiano Serlio in his *Second Book of Architecture* (1545, Eng. trans. 1611); this was elaborated by Leone de' Somi in the *Dialoghi in materia di rappresentazioni sceniche* (*Dialogues on Stage Affairs*; c. 1550). Both describe the use of torches behind glasses of coloured water for lighting effects. Serlio adds that the light can be intensified by setting a bright basin behind the torch. These lights were on stage, for instance behind windows, and De' Somi claimed that the glasses were first used to screen the direct light from the audience's eyes. He advocated concealing the light sources as far as possible and having few lights in the auditorium set well back behind the audience so that the stage should appear bright by contrast.

Nicola Sabbatini's *Pratica di fabricar scene e macchine ne' Teatri* (*Manual for Constructing Theatrical Scenes and Machines*; 1638) describes how to make various types of lights and a fuse to light the lamps simultaneously, and illustrates a dimmer, which descended over the candles. He describes footlights behind a small parapet at the front of the stage, but he preferred side lighting and lighting behind the "heavens." Besides the drawback of smoke and smell, with footlights "one can see better the costumes of the actors and the dancers," he wrote, "but . . . their faces seem so pale and wan that they look as though they have just had a bad fever."

The earliest illustration of lighting in the English theatre is the frontispiece of Francis Kirkman's *The Wits* (1672). Six double-wick oil-float lamps and two chandeliers with eight candles each lighted the stage.

Throughout the Baroque era the stage was lighted by chandeliers that remained in view whatever the scene below. The actor-manager Tate Wilkinson in his *Memoirs* describes these on the English Restoration stage. Chandeliers over the stage appear also in pictures of a leading Parisian theatre, the Hôtel de Bourgogne, in 1688 and in a painting of the Comédie Française about 1670; the latter view also shows footlights, 34 candles along the edge of the apron stage, their glare kept from the audience by metal shades.

Though David Garrick did not introduce footlights to the English theatre—they were already in use at the Drury Lane—contemporaries were clear that the lighting reforms he brought about in 1765 with the help of his scene designer P. J. de Louthembourg were a sensational improvement. He abolished the stage chandeliers (visible to the audience and obscuring the view from the gallery) and at the same time improved the quality of the lighting while concealing its source. Garrick relied mainly on sidelights (on the prompter's side only) mounted all the way up so-called wing ladders—an arrangement already in use but only as a subsidiary source of light. These he supplemented with concealed footlights and perhaps with concealed lights above the stage.

The introduction of the Argand burner (*q.v.*) provided a brighter light source; but before it had time to influence the technique of stage lighting, it was superseded by gas.

**Gas.**—Illuminating gas first was used regularly to light the stage in 1816, in the New Theatre, Philadelphia. The gas had to be manufactured by the theatre itself, at great expense; it also required miles of piping. Several London theatres soon adopted the new medium, but it did not come into common use until about 1850. Gas permitted for the first time control of all lights from one central location; it could be turned off and on either at the mains or with secondary valves from a "gas table" near the prompter. The original gas burners were open flames or flames in glass chimneys (superseded after 1887 by the more efficient Welsbach mantle); blazing alcohol wads on long poles were used to light the jets. Chief among the defects of this system was the danger of fire: theatre fires promptly doubled in the U.S., Great Britain, and France, and the thin costumes of dancers sometimes caught fire from the footlights. Fire regulations, therefore, were established, which fixed the position and number of burners and made the presence of guards compulsory.

Until the reforms introduced by Henry Irving at the Lyceum, which he acquired in 1878, little thought was given to the artistic potential of gas, which was accepted for its brighter illumination and its controllability. Irving experimented with realistic effects. The auditorium was darkened, and he used individual lights to achieve more plastic illumination onstage; *e.g.*, lights picked out the lovers Romeo and Juliet although the bedroom scene was set at night. He also devised an elaborate system of drawing coloured silks and screens in front of his lamps for colour mixing, and later he employed spotlights.

**Limelight.**—The calcium ("lime") light, invented by Thomas Drummond in 1816, may have been used in the theatre by 1837 and was widely used by the 1860s. A block of calcium heated to incandescence in jets of burning oxygen and hydrogen provided a soft, very brilliant light that could be directed and focused. (In England front-of-balcony lights may still be called limes.) Limelights were mounted on adjustable stands and could follow actors and dancers with localized light.

**Electric Light.**—*Arc Lamps.*—The arc lamp provided the earliest form of electrical lighting in the theatre. Invented by Sir Humphry Davy (who also contributed greatly to the development of the limelight) in 1809, it did not come into general use in the theatre until about 1870, although it had been used experimentally by M. Duboscq and Léon Foucault in 1846 in a production of the *Prophète* at the Paris Opéra. Duboscq went on to develop a lightning machine (still used), a rainbow projector, and a luminous fountain, all using arc light.

The Jablochkov candle, a light arcing between two parallel

sticks of carbon, was first used theatrically in the Paris Hippodrome in 1878, and 52 were installed in a theatre at Lyons, the Bellecour, in 1879. It was, however, never widely used as it could not compete with the incandescent lamp.

**Incandescent Lamps.**—The invention of the carbon-filament incandescent lamp by Thomas A. Edison in 1879 brought a relatively high-powered, easily controlled, and comparatively safe light source to the theatre. Light could now be used as a fully plastic medium, coloured, and varied in form and intensity in ways of which earlier designers had only dreamed. The synthesis of acting, music, scene design, and light into the composite whole advocated by Richard Wagner could at last be achieved.

In 1880–81 the Paris Opéra experimented with the first theatrical installation of electricity (completed by 1886). The Savoy Theatre, home of Gilbert and Sullivan, in London and the Bijou Theatre in Boston had electricity by 1882. The Landestheater in Stuttgart, the Residenztheater in Munich, the Staatsoper in Vienna, and the Staattheater in Brünn (now Brno) were electrified by 1883; the People's Theatre on the Bowery in New York City, by 1885. Most theatres had installed electricity by about 1890 (although at first gas was retained along with the newer medium).

The early electric globes (those with carbon filaments) gave a relatively dull light, orange in colour. Improved methods of construction, however, increased efficiency and decreased size. Today 750-w. and 1,000-w. lamps only 1½ in. in diameter are common in spotlights, and there are single globes up to 10,000 w.

New equipment was designed to make efficient use of these light sources; for example, by the American Steele MacKaye (*q.v.*) in the last quarter of the 19th century in the Madison Square and Lyceum theatres in New York. The Italian Mariano Fortuny, working in Germany, developed about 1902 the *Kuppelhorizont*, a half dome made of silk or plaster, from which light was reflected upon the whole stage; it is still the most perfect means of simulating natural sky backgrounds. Obsolete because prohibitively expensive, this has been developed into the cyclorama, a semicircular plaster or taut canvas wall surrounding the back of the stage, sometimes 90 ft. high, which can be lighted from top and bottom to give sky effects.

In the U.S., David Belasco and his electrician Louis Hartman began lighting experiments in 1879. Hartman developed the first practicable lensed spotlight, using simple plano-convex lenses to concentrate the rays. Belasco almost eliminated footlights, substituting spotlights in the auditorium and wings. His standards of realism remain a major influence in modern productions.

With the development of new lamps, lens systems other than Hartman's were possible. By using a tubular instead of a globular lamp, the extremely short-focused Fresnel lens (invented in the 1820s) could be used in the theatre; this provided a smooth, brilliant throw of light with no clearly defined edge, which was very valuable in blending illumination in acting areas (*see fig. 1*).

## MODERN STAGE LIGHTING

**Spotlights.**—The most important single instrument in stage lighting today is the ellipsoidal framing spotlight (see fig. 1). The light is gathered and redirected by the reflector, which passes the rays generated at one focal point of the ellipse through the other. A gate (aperture), adjustable in size and shape, is placed between the two focal points, and one or two objective lenses then project the image of the aperture onto the area to be illuminated. Fields of even intensity are produced, the beam may be shaped, hard or soft edges are possible, and efficiencies comparable to those of the Fresnel lens are obtained. With the framing spotlight, light can be masked perfectly, kept away from the orchestra, scenery, or draperies, and projected with extreme accuracy to the exact spot where it is required.

Follow spotlights have advanced greatly from the days of the limelight. The carbon arc still remains the most brilliant and smallest light source, but modern arcs operate at much lower amperages than formerly, with resultant increases in brilliance and lowered installation and operating costs. A modern 10-amp. follow spotlight will provide a very brilliant 3-ft. circle at a distance of 100 ft., or will flood a 40-ft. stage at the same distance. Such lights have selective colour controls and are balanced for smooth, easy operation. Other arc spotlights ranging from 20 to 200 amp. are used for all productions requiring a brilliant circle of light following the performers. Incandescent follow spotlights, having the same general lens and colour systems and commonly provided with 1,500-, 3,000-, or 5,000-w. lamps, are used for shorter throws.

**Floodlights.**—While spotlights are the basis of modern stage lighting, various forms of floodlights give general illumination and cover wide areas. Footlights are one form of floodlight; borderlights, standard in most theatres today, are another. Present-day foots and borders either have individual reflectors of spun aluminum or use lamps with internal reflectors. Individual colour filters are provided for each lamp.

Single floodlights have always been used for illuminating off-stage areas, cycloramas, and similar large expanses where detailed light is not required or desired. The earliest floodlights were the so-called bunch lights utilizing clusters of candles, torches, or small incandescent globes. They were followed by the olivette, a square box-type reflector on a portable stand, using a single large lamp. The modern stage floodlight has a spun aluminum reflector, with a soft matte surface, and usually a 1,000- or 1,500-w. lamp. It may be placed on a stand or hung overhead. Because of their shape, such lights are usually referred to as scoops. Mounted singly or in groups, they provide smooth, featureless light over broad expanses.

**Light Control (Dimming).**—Control of illumination has always been a prime requisite for the theatre. Opaque slides and screens, blasts of air to extinguish candles, and other devices preceded the valves of the gas table and laid the foundations for the electric dimmer. The first electric dimmers were water barrels with two metal plates immersed in a weak brine solution. One plate rested at the bottom of the barrel; the other could be raised and lowered, increasing or decreasing the distance the current had to pass through the brine and thus varying the brilliance of the light. The system worked, after a fashion, but produced extremely uncertain results and much bad odour.

Resistance dimmers, consisting of a coil of resistance wire tapped at many points, with a turning contact touching the taps at successive points, provided the next type of dimmer. Resistance dimmers simply turned radiant energy from light into heat, diverting the electricity from one use to another. In spite of their large size, hotness, and comparative lack of sensitivity, they were the most widely used dimmers for 50 years and have by no means been entirely superseded today. The fact that they will control only loads near their rated capacity is a disadvantage, but they will operate with equal efficiency on either direct or alternating current.

The dimmer in commonest use at the present time is the autotransformer, which acts as a valve rather than as a diverting device, not utilizing the current when the lights are dimmed. Auto-

transformers are efficient from their full rated capacity down to almost zero, are cool and silent in operation, and provide extremely smooth changes in light intensity. They are manufactured in sizes ranging from 100 to 8,000 w.

Resistance and autotransformer dimmers may be operated either manually or by motors. In the average manually operated autotransformer dimmer board (see fig. 2), the dimmers may be selectively interlocked mechanically into banks (groups), which in turn may be interlocked into a grand master. In motor-operated dimmers, switches controlling the motors select the direction in which they travel, either dimming or brightening the lights. Because of their slow operation, motor-operated dimmers are seldom used for the stage but are common for auditorium lights.

BY COURTESY OF KLEIGL BROS. UNIVERSAL ELECTRIC STAGE LIGHTING CO.

FIG. 2.—(LEFT) MANUAL AUTOTRANSFORMER DIMMER BOARD; (RIGHT) TYPICAL PATCHING PANEL FOR A LARGE DIMMER BOARD

A more modern addition to the field of theatrical dimmers is the magnetic amplifier. A saturated coil reactor was first used at the Earls Court Theatre in London as early as 1890, but it was not perfected for stage use until the middle of the 20th century. Dimming is accomplished entirely electrically, without moving parts except in the control devices. Magnetic amplifiers are operated remotely by low-voltage circuits; therefore, the actual dimmers may be placed at any convenient location and the console located so that the operator can see the stage. Magnetic amplifiers are long lived, have low maintenance costs, and operate silently.

One of the most widely known systems of electronic dimming was invented by George C. Izenour and carries his name. This board uses a remote console and preset panel that contain all switches and various controls for selecting the intensity of each circuit. Circuits may be operated singly or combined in an endless variety of groups. As in the magnetic amplifier boards, the actual tubes are remote from the console, which can be located where the operator has a clear view of the action. The Izenour system can handle varying loads on any circuit, is highly flexible, and responds very rapidly. A certain amount of noise is generated in operation, but this is of comparatively minor importance if the tube racks are located far enough from the stage.

During the 1960s the silicon-controlled rectifier dimmer passed all other forms and became the most popular and widely used. It employs two P-N-P-N semiconductor devices connected together (see TRANSISTOR) and with the lamp load in such a manner that an electric signal will control the conductivity of the P-N devices and thus the brilliance of the light. Silicon-controlled rectifier dimmers (SCR) have all the advantages of other forms and in addition are smaller, lighter, and require less maintenance. Remote control is efficient at low voltages, making installation simple and inexpensive. SCR dimmers are manufactured in capacities ranging from 1,800 to 6,000 watts. Lightweight, compact, portable dimmer systems are now entirely practicable, a condition never before obtainable in satisfactory manner.

An essential part of almost all modern dimmer switchboards is a patching panel (see fig. 2), which makes it possible to connect

any load circuit in the theatre to any dimmer. Each dimmer has a number of outlets, into which cords connected to the lights are plugged. Changes in patching make it possible to use the same dimmer for different loads during a single production. Thus, every dimmer can be utilized to its maximum, and the board is smaller and more efficient.

**Placement of Light Sources.**—Dividing the stage into pools provides a basis for focusing. The pools are usually located downstage (toward the front) left, centre, and right; then upstage (toward the back) left, centre, and right. Spotlights from the ante-proscenium beam (located in the auditorium ceiling about 50° up from the curtain line), balcony, borders, and sides are focused to cover each pool from several angles and in different colours. The director can then call for a single pool complete, or for any of its components, or for any combination of one or more pools. As it requires a minimum of change between shows, this system works well in a permanently equipped theatre where many varied productions are undertaken in quick succession. For professional productions, however, it limits both designer and director by forcing them to adapt areas set arbitrarily by the lighting.

In most cases, acting light comes from the front and above. Banks of ellipsoidal framing spotlights in the ante-proscenium beam are considered the ideal basic source. Following them for choice, or if necessary substituting for them, are lights on the balcony rail, then "boomerang" spotlights from the sides of the auditorium. A completely equipped theatre has all three sources.

Ante-proscenium beam lights overcome confusing shadows on the scenery, which are always present when balcony lights and footlights are used alone. Side lighting provides "modeling," giving the actor a third dimension of light and avoiding the flatness of straight illumination. Lighting from the auditorium with long-range units has made footlights practically obsolete, though they are occasionally used for blending and toning spotlighted areas and still illuminate backdrops and curtains.

The so-called concert border or first pipe is a bank of spotlights, usually with Fresnel lenses, suspended immediately behind the front curtain. These may be augmented with framing spotlights and borderlight sections, usually called "X-rays" when placed in this location. Trees (towers of spotlights) behind the tormentors (screens that mask the space between the front edges of the set and the proscenium arch) provide supplemental and modeling lights. Additional pipes overhead hold more spotlights and floodlights, as the production requires, either for direct lighting or for backlighting. Backlighting is particularly important in giving finish and clarity to the illumination. Floodlights for cycloramas, offstage areas, doorways and windows, and other specific areas are placed above, below, or beside each such area. Projectors, special-effects lights, and detail lights may be anywhere on the stage or in the auditorium. Follow spotlights are usually operated from the projection room or balcony but may be on or above the stage.

The growth of large outdoor productions during the 20th century has led to much experimentation in long-range lighting. Since it is usually impracticable to have a proscenium arch outdoors, the lighting units must be placed at great distances from the stage, either at the back of the seating area or at the sides on towers. Beam-projector units, commonly referred to as "sunspots," have been found most efficient for this type of installation, where throws may range up to 200 ft. Beam projectors have no lenses, depending for their brilliance on large mirrored reflectors. Detailed lighting can be provided with high-intensity arc spotlights. The sunspots are supplemented by smaller units in the footlights and concealed within the setting.

**Colour.**—*Technique.*—Obtaining satisfactory colour in stage lighting has always presented problems. Fortuny and his contemporaries used coloured silks and reflectors, but high intensity was impossible with these techniques. Lamp dips and lacquers applied directly to the glass were developed almost as soon as the electric light, but these cannot withstand high temperatures. So-called natural colour lamps, manufactured with permanent dyes in the glass, provide satisfactory colour but are quite expensive, are limited in colour range, and have a very high light loss.

Gelatin, in the form of transparent coloured sheets that are

fitted in front of lighting units, is the most widely used colour medium. It is available in a wide range of colours and is flame resistant and inexpensive. After several hours' use it becomes brittle and fades. Since it absorbs water readily and then tends to melt, it is very unsatisfactory in damp localities. A newer medium is plastic. It is impervious to water, fades more slowly than gelatin, is heat resistant, and is stiff enough to be used in small lights without a reinforcing metal colour frame. The range of colours is about the same as that for gelatin, and the price is much higher. The greater expense is offset, however, by the longer life and lowered costs of making changes.

Glass is used in borderlights and footlights but has never become general in spotlights and floodlights. Permanence of colour and physical strength, its chief advantages, are offset by fragility, high initial expense, and narrow colour range. Breakage from heat is also a drawback, though asbestos mountings and expansion cracks have largely overcome this defect. Colour frames for border- and spotlights are usually so designed that glass can be used for general applications, with gelatin substituted for special productions.

Lighting with primary colours has found wide favour in Europe and to some degree in the United States. By combining spectroscopically true shades of red, green, and blue, white light can be created. While this is of unquestioned value, particularly on sky cycloramas, it is generally more efficient and economical to use a colour medium of the desired shade than to create the colour by mixing.

**Design.**—Generally speaking, it is usual to have warm colours coming from one side of the stage and cool from the other, since this is normal in natural lighting. Lighter colours are used on faces; darker, richer tones on settings. In the legitimate theatre the setting is usually lighted sufficiently by spill light from the acting areas. In more spectacular productions, such as opera and ballet, lighting on sets and backdrops is important.

For lighting faces the most widely used colours are light flesh pink, light lavender, and light scarlet, called, respectively, flesh, surprise pink, and bastard amber. These are augmented with steel blues, light straws, and occasionally deeper colours for acting areas. For backgrounds and sets a much wider range of colours is used, including several shades of blue and blue-green, magenta, green, amber, and red.

**Special Effects.**—Special effects are provided by a wide variety of electrical and lighting devices, ranging from mica slides projected by ordinary ellipsoidal spotlights to elaborate moving projections, such as rippling water, drifting clouds, and dancing flames. The effects are generally painted on mica disks that revolve in front of a spotlight, an additional objective lens being placed in front of the disk to focus the moving image. Such projection may come from the front, back, or, occasionally, sides of the stage.

So-called black-light phenomena have become highly popular special effects. Costumes, scenery, and properties are dyed or painted with pigments containing fluorescent materials; when exposed to ultraviolet light from which the visible rays have been filtered, the prepared objects show up vividly against an almost invisible background. Theatrical sources of black light are varied, the most widely used being mercury-vapour lights behind deep-purple glass filters, and black-light fluorescent tubes. Arc spotlights are also effective sources. Since little ultraviolet radiation is present in the standard incandescent lamp, ordinary spotlights and floodlights are seldom used. Combinations of black and visible light are used to produce many unusual effects.

Shadow projectors are old in principle, most present-day units being based on the apparatus developed by Adolf Linnebach and commonly known as the Linnebach projector. The unit consists of a deep box painted black inside and utilizing a concentrated-filament high-intensity lamp. One side of the box is open and contains a glass or mica slide carrying the design to be projected. Sharp projections are not possible, but silhouettes and wide outlines can be provided over wide areas. A modern light of this type contains a wide-angle lens system and provides a very clear delineation for either front or rear projection. In the latter case a drop (translucent screen) is required.

**STAGG, AMOS ALONZO** (1862–1965), U.S. football coach, known as the “grand old man of football,” had the longest coaching career in the history of the sport. Born on Aug. 16, 1862, in West Orange, N.J., he attended Yale University, where he played end and was chosen to the initial All-America team selected by Walter Camp (1889). He also was an outstanding baseball pitcher and rejected several offers to turn professional. Graduating with a divinity degree, he decided not to become a minister and instead entered Springfield (Mass.) College, where he coached and also played on the team. In 1892 he went to The University of Chicago as coach and head of the physical education department. He soon made the Maroons one of the great football powers of the early 1900s and was credited with more innovations than any coach of his era, some of which were the end-around play, the hidden-ball trick (since outlawed), huddle, shift, man in motion, and the practice tackling dummy. Five of his Chicago teams were undefeated, six of them won Western Conference championships. At the age of 70 he retired from Chicago (1933) with an overall record of 268 victories and 141 losses. In 1934 he became coach of the College of the Pacific at Stockton, Calif., and he was named coach of the year in 1943. In 1946 he went to Susquehanna (Pa.) College to help his son, head coach Amos Alonzo Stagg, Jr., in an advisory capacity, and he also was an adviser at Stockton (Calif.) Junior College from 1953 to 1960. Throughout his 71-year coaching career, he constantly emphasized character development, devotion to clean habits, and a healthy mind and body. Stagg was among the first to be chosen to the Football Hall of Fame (1951) and the only one to be selected as a player and a coach. Stagg died at Stockton on March 17, 1965. (D. Sr.)

**STAGNELIUS, ERIK JOHAN** (1793–1823), one of the outstanding poets of the romantic movement in Sweden. The son of a pastor who became bishop of Kalmar, he was born on the island of Öland, Oct. 14, 1793. He had no regular schooling, but received a good grounding in the classics. After studying law at Uppsala University, he became a civil servant in Stockholm in 1815. Little is known of his later life. He seems to have led a very isolated existence, and it is doubtful whether the ardent love poems to “Amanda” were actually addressed to a real person. His health was undermined by heavy drinking and he died poor and lonely at Stockholm, April 3, 1823.

In his earliest known poetry, Stagnelius adopted a neoclassical style and showed an Epicurean attitude to life. He remained consistent in his aspiration for clear, concise form; his sensuality also persisted in his choice of imagery, although after 1815 Epicureanism gradually gave way to extreme philosophical idealism. Some of the poems from his later theosophic period are difficult to interpret. He was influenced not only by F. W. J. von Schelling, but by such mystics as Jakob Böhme, L. C. de Saint-Martin and Emanuel Swedenborg. The underlying elements of his philosophy are derived from various neo-Platonic and Gnostic systems. The human soul, or Anima, has left its home in the spiritual world, Pleroma, and is subject to Demiurgos, the ruler over sensual reality. This realm is felt to be a bewitched and enchanted world, a desert or a prison, whence man, like the rest of creation, longs to return to his heavenly home.

Stagnelius' poetic inspiration is wide-ranging and he is master of an unusual variety of forms. Among his notable works are a monumental epic in hexameters on the Christianization of Russia, *Wladimir den store* (1817), and several plays which, though lacking in dramatic intensity, contain passages of brilliant rhetoric and melodious verse. Some are set against a background of early Scandinavian mythology, others (e.g., the blank verse play, *Bacchanterna*, 1822) have a classical setting. But Stagnelius is, above

all, a lyrical poet. Of a more metaphysical cast of mind than Keats, of whom he was an almost exact contemporary, he shared with him unusual lyrical intensity and powers of illumination.

One of the few works published in his lifetime was the collection of poems *Liljor i Saron* (1821). The critical edition by F. Böök, 5 vol. (1911–19), has an indispensable commentary.

See F. Böök's monograph on Stagnelius (1919; abbreviated and rev. ed., 1954). (S. B.)

**STAHL, GEORG ERNST** (1660–1734), German chemist and physician, was known chiefly for his doctrine of phlogiston (see CHEMISTRY: *History of Chemistry: The Phlogiston Theory*), which held that “phlogiston” was the material of fire. He was born on Oct. 21, 1660, at Ansbach, and graduated in medicine from Jena in 1684. He became court physician to the duke of Saxe-Weimar (1687), professor of medicine at Halle (1694), and physician to the king of Prussia at Berlin (1716), where he died on May 14, 1734.

The essentials of his theory were derived from Johann J. Becher (1635–82). Stahl also propounded a view of fermentation, which, in some respects, resembles that supported by Justus von Liebig 150 years later. He was a firm believer in animism. In his youth he believed in alchemy, but later he warned against its frauds. He observed that acids are of different strengths, that the basic component of common salt differs from that of potash, and he recognized the particular nature of the earthy constituent of alum. His views of combustion were first presented in his *Zymotechnia fundamentalis* (1697). His chief medical treatise was *Theoria medica vera* (1707). His principal chemical work was *Fundamenta chymiae* (1723).

See C. W. Beck, “Georg Ernst Stahl . . .,” *J. Chem. Educ.*, vol. 37 (1960). (R. E. O.; X.)

**STÄHLBERG, KAARLO JUHO** (1865–1952), the architect of the Finnish constitution and the first president of independent Finland. He was born at Suomussalmi on Jan. 28, 1865. A lawyer by training, he made legality the keynote of his political thinking. Joining the Constitutionalist Party, he was elected to the Diet in 1904 and entered the government of the autonomous Grand Duchy of Finland in 1905 but resigned office in 1907. From 1908 to 1918 he was professor of administrative law at the University of Helsinki.

One of the more prudent Constitutionalists, Ståhlberg consistently gave proof of his democratic outlook: he was among the first to demand universal and equal suffrage. His draft of a republican constitution (1917) became the basis of the actual constitution of 1919, still in force in the mid-1960s. On the reshuffling of the political parties when national independence was achieved, Ståhlberg joined the National Progressive Party. Elected president of the new republic (1919), he set the pattern for his successors by making full use of his constitutional powers. He did his utmost to narrow the gap between “Reds” and “Whites” after the Civil War. At the end of his term (1925) he did not seek reelection, as he thought that the right would become reconciled to the republic sooner if he stood aside. He was a victim of personal violence during the outbreak of right-wing extremism in 1930. He was defeated by two votes in the presidential election of 1931 and by one vote in that of 1937. He died in Helsinki on Sept. 22, 1952. (See FINLAND: *History*.) (E. K. I. J.)

**STAINED GLASS.** All coloured glass is, strictly speaking, “stained” by the metallic oxide added to it in the process of manufacture, but the term is popularly, as well as technically, understood to refer to stained glass windows. In the great period covering the development of the narrative or pictorial window, with which this article is primarily concerned, the stained glass window was composed of an ensemble of pieces of glass, coloured or otherwise, held together in a framework of leading and painted to form an image or pattern design. Neither leading nor painting was an essential feature of the earlier mosaic window, nor of the continuation of this abstract tradition into Islamic architecture, where jewel-like glass is usually set in cement tracery. Contemporary stained glass, like contemporary art in general, is characterized by an experimental approach that precludes any narrow technical definition.

This article deals with the early development of stained glass, then with the techniques of assembling and painting windows, and finally with the history of stained glass windows from the 12th century to modern times.

### EARLY DEVELOPMENT

As a substance, glass itself is of considerable antiquity, and glass objects dating from the 3rd millennium B.C. have been found in both Egypt and Babylonia. The commercial application of the art of glass blowing, possibly a Syrian invention in the first place, was decisive in the development of the glass window. It was probably introduced into the Roman world in the 1st century B.C. By the 1st century A.D. improvements in manufacturing techniques had resulted in the provision of larger glass window panes and a consequent increase in the size of windows. This development was not restricted to Italy. Window glass has been discovered at almost every Romano-British dwelling site, ranging chronologically from the mid-1st century to the end of the 4th century A.D.

The writings of the Fathers of the Latin church, Lactantius, (before 330), Prudentius (before 413), and St. Jerome (before 420), mention glass windows in the early Christian basilicas, and it is recorded that Pope Leo III (795-816) provided windows of glass, of different colours, for St. Paul's church at Rome. The earliest record of glazing in an English church is found in the *Life of St. Wilfrid* (q.v.), Archbishop of York (c. 634-709). His biographer, writing shortly after the saint's death, records how Wilfrid restored the church at York, probably between the years 669 and 671, and that "by putting glass in the windows he prevented the birds or the rain from getting in." This glass was almost certainly obtained from abroad, as a few years later, about 675, Benedict Biscop, abbot of Monkwearmouth, imported glaziers from Gaul to glaze the windows of his monastic church, and the Venerable Bede in recording this observes that the craft was previously unknown in Britain. Excavations carried out in 1962 at Monkwearmouth recovered a number of pieces of window glass in various colours, green, blue, amber, and red, and the edges of several pieces were grozed (i.e., cut) for fitting into a window. None of the pieces, however, were painted and there is no evidence of the overall design. This glass, which is certainly pre-9th century in date, may have been part of Biscop's foundation (see BENEDICT BISCOP, SAINT). In form these early windows varied considerably: the actual window openings were at first filled with thin sheets of marble, alabaster, or gypsum, or even wooden boards, which were pierced with holes, coloured glass being inserted into these holes. In addition to glass other materials were used for the same purpose, thin strips of alabaster set in a bronze frame being not infrequent. This form of window design persisted even in Western Europe into the Romanesque period, and 11th-century examples are to be found at Torcello Cathedral and in the church of San Miniato at Florence. The employment of leading to hold together the pieces of glass in a window opening was possibly used contemporaneously with the above early methods, since leading which may have been used in window glazing dating from the 4th century has been uncovered in excavations.

The use of leading was of fundamental importance in the development of the figurative window, for this strong yet pliable substance can hold together the most intricately shaped pieces of glass, thus giving the glazier considerably more freedom in imaginative design and making the narrative window possible. The earliest example of a leaded window design was a small panel at Séry-les-Mézières (Aisne, Fr., destroyed in 1918) which was probably of the 9th century. It appears certain that as at Séry-les-Mézières many of these early windows contained coloured glass arranged in comparatively simple decorative designs, with little use of the painted design, and there is no documentary evidence even to suggest the existence of pictorial windows until the 9th century, when several rather vague references testify to the appearance of figures in German and French glass. In the 10th-century history of the church of St. Remi at Reims, rebuilt by Adalbéron, Bishop of Reims (969-988), the monk Richer, writing about 995, states that the windows contained various stories.

Other early evidence regarding pictorial windows depends on fragments discovered in excavations. Those carried out in 1937 at Lorsch (Ger.) recovered the remains of what might be the earliest pictorial window extant. It was possible to reconstruct from fragments a head of Christ, which shows some stylistic affinity with Carolingian manuscript paintings and probably dates from the 9th, 10th, or 11th century. Another head excavated at Magdeburg (Ger.) might be connected with the building of the cathedral founded by Otto the Great in 955 and is possibly before the year 1000 in date. Somewhat later is the well-known head of Christ from Wissembourg, now in the Strasbourg museum, which is to be dated c. 1070-1100, but unfortunately its painted surface has been reworked by a modern restorer. The earliest complete pictorial windows extant are those containing five figures of prophets in Augsburg cathedral. Their date has been the subject of some dispute in the past but they are now widely accepted as belonging to the beginning of the 12th century.

The evolution of the stained glass window was a slow process. Both texts and excavation testify to the existence of stained glass windows before the 12th century, but the textual references suggest that it was a rather exceptional form of decoration, creating much admiration and no little astonishment. Also, in Carolingian and Romanesque architecture the window openings, partly for structural reasons, were small and few in number, so that polychrome decoration was naturally concentrated on the large mural areas and the vaults rather than on the windows. It was not until the developments of the 12th century that glass painting became a major art form and in Northern Europe the most important single element in church decoration.

Although the pictorial stained glass window is normally regarded as the invention of Western Europe, where its development can be followed with reasonable coherency from the beginning of the 12th century onward, there is still much that is obscure about its earlier evolution. The discovery during excavations by the Byzantine Institute in Istanbul (Dumbarton Oaks Papers 1963) of stained glass windows, apparently deriving from a tradition independent of that in the West and datable before 1136, adds to the complexity of the fragmentary evidence already cited.

### TECHNIQUE

The account provided by Theophilus (q.v.) in his treatise *De Diversis Artibus* ("The Various Arts,") probably written between 1110 and 1140 in northwest Germany, gives a picture of the general technique of assembling and painting a window that remains valid throughout the great period of the stained glass window from the 12th to the 15th century.

A full-size working drawing of the finished design for each panel was first made on a whitewashed board and the colours of the component parts were indicated by letter. Pieces of glass were then shaped to the outlines required by the design: first rough-cut from sheets of glass using an iron with a red-hot point which when pressed onto the glass cut with ease in any direction, and then trimmed to the exact shape using a grozing iron, a flat tool with a notch in one end. These shaped pieces were then laid over the drawing on the table so that the details of the design could be painted on the glass with a pigment of dark opaque enamel, consisting of powdered glass mixed with a metallic oxide (iron or copper) in a solution of wine or urine. Paintbrushes were made from animal furs, the tails of martens, badgers, squirrels, or cats, or even the mane of an ass. The effect of shadows and highlights could be produced on faces and draperies by varying the thickness of the brush strokes and using thin washes of a medium tone. The overall design could be further enhanced, particularly on draperies and backgrounds, by covering the glass with a thin wash of enamel and then picking out a decorative pattern or foliage design, using the end of the paintbrush or a sharpened stick. On completion of the painting the glass was placed in a pan, layers of glass alternating with whiting (ash or quicklime), and fired in a kiln to fuse the painted enamels. When the firing was over and the glass had cooled, it was rearranged on the table prior to leading. The strips of lead used for joining the pieces of glass together had an H shape in section and were cast in iron or

wooden molds. When the leading, cut to the required length and shape, had been inserted between the pieces of grozed glass it was then soldered together at the points of junction, and cement or putty was forced between the leaves of lead and the glass to make the whole panel watertight. The panels were fixed in place in the window by means of leaden strips soldered to the leads on the outside surface of the glass and attached to iron saddle-bars let into the masonry. Large windows were made in smaller units and these units fitted into an iron framework or armature, which often formed a geometric pattern that was incorporated into the overall design of the window. The basic function of the armature was, however, structural: it supported and distributed the total weight of the glass, for without it a large window would collapse.

From the 12th to the 15th century variations in the technique of stained glass were confined to a few important refinements, the most important of which was the discovery in the first decade of the 14th century that glass could be stained yellow by using a derivative of sulfide of silver. This stain was invariably applied to the outer surface of the glass, forming on it a very thin transparent film which varied in tone according to the texture of the glass and the heat of the furnace. In addition to its use on white glass it could be applied to coloured glass; *e.g.*, its use on blue glass produced a brilliant green. This discovery saved the glass painter much time and labour by eliminating a certain amount of leading. For example, a yellow crown could be stained on the same piece of glass as its wearer's head. Similarly, decorative patterns and details of foliage decoration, particularly on the white quarries (or diamond-shaped panes), could be picked out in yellow stain.

Medieval coloured glass is known as "pot-metal" glass because in the primary stages of its manufacture the glass and colouring material (generally a metallic oxide) were fused together in the melting pot. An exception to this rule is ruby glass, which was so dark that to obtain sufficient translucency the glass was "flashed"; that is, clear glass while still pliant was dipped into molten coloured glass. The glass when formed into a sheet was thus coated with coloured glass on one side only. Detailed effects, unhindered by intricate leading, could then be achieved by grinding away part of one of the layers. This technique was first practised in the late 13th and early 14th century; one of the earliest extant examples at Mussy-sur-Seine (Aube, Fr.) shows a blue groundwork diapered with ruby roses with white centres, each rose being a single piece of glass. This class of work is, however, more common in the 15th and 16th centuries; as later glass was much thinner the practice of this type of refinement was technically easier to execute.

Eventually in the middle of the 16th century the technique of painting in enamel colours on glass began to be of major importance. In this method the various colouring matters made from the metallic oxides, copper for green, cobalt for blue, manganese for purple, and so on, are mixed with flux, which is soft ground glass with a melting point lower than that of the glass to be painted. After firing in the kiln, the glass is allowed to cool and the flux, which has been melted in the process, hardens and together with its colouring matter adheres closely to the glass. For some time this new technique went side by side with the old technique of pot-metal glass. The political disturbances of the mid-17th century created a scarcity of pot-metal glass and gradually the ancient methods were replaced by the new technique of painting in enamel colours.

In the Middle Ages ecclesiastical art was primarily didactic. The subjects painted in the windows played an important part in the expounding of the Scriptures and the glorification of the church and its saints, and it must be assumed that clerics supplied the master glazier with a program to which he had to conform. A 13th-century roll in the British Museum contains a series of circular drawings illustrating the life of St. Guthlac (Harley Roll Y 6). These drawings might have been intended as a model for a glazier, but the scenes could equally well have been expressed in wall paintings, sculpture, or metal work. Our knowledge is more complete for the later Middle Ages. The glazier was given written instructions from which to prepare provisional sketches that were sub-

mitted for the patron's approval before being redrawn in actual size to form the final cartoon. The provisional sketch was known as a *vidimus* (literally, "we have seen"). One example of such written instructions is extant. It is the program for a window given by Henry VII to the Grey Friars church at Greenwich (British Museum Egerton MS. 2341). A typical entry is that for St. Audry: "Seint Audry, a kynge's daughter shryned at Ely. Make her in thabbytte of a Nonne wyth an opyn Crowne crowned with a croyse in her ryght honde, a booke in her left honde." The Greenwich roll blazons the shield of arms appropriate to each figure and to prevent misunderstandings, each shield is also painted in the left hand margin of the roll. There is ample evidence to show that by the 14th century it was the practice of glaziers to have a stock of finished cartoons, executed on parchment or paper, which could be adapted for different glazing schemes. That these cartoons were used and reused over a long period can be deduced from the will of William Inghish, a York glazier who died in 1450, in which he bequeathed to his son Thomas "all the cartoons belonging to my work."

It is evident that in the later Middle Ages the master glazier's workshop was a highly organized enterprise, capable of producing various classes of designs, according to the expense his patrons were prepared to incur. John Prudde, glazier to King Henry VI, provided four main types of design at varying prices for the glazing of the parish church and college chapel at Eton between the years 1445 and 1450. He charged eightpence halfpenny a foot for figures set on a simple groundwork of quarries, while heraldic work of shields of arms set on quarries cost tenpence a foot and other glass wrought with different figures and borders was one shilling (twelve pence) a foot. Subject windows, presumably with narrative scenes, were supplied at two prices, one at one shilling and two pence a foot, the other at one shilling and fourpence.

Although the donor, cleric or layman, exercised considerable influence over the choice of subject and its manner of representation, the finished design was essentially the creation of the master glazier. The latter was often an artist in his own right, expressing in the formal language of his own technique the artistic aspirations of his time.

## HISTORY

### 12TH CENTURY

In the 12th century the production of stained glass windows, particularly in Northern Europe, was considerable, and regional schools begin to be discernible.

**France.**—A number of important regional schools of glass painting emerged, one of the earliest of which was in western France. The most important products of this group include the Ascension window at Le Mans, *c.* 1145, and the Crucifixion window in Poitiers Cathedral, *c.* 1165. In Champagne appeared another quite distinct group, whose best work is found in the Redemption and St. Stephen windows at Châlons-sur-Marne, *c.* 1150–60, together with the very important later windows at Saint-Remi at Reims, *c.* 1190.

The most important workshop in the Île-de-France was connected with the rebuilding of the choir of Saint-Denis, undertaken by the Abbot Suger, 1140–44. Only fragments of these windows are left, but the three windows of the west facade at Chartres are later products of the Saint-Denis workshop, about 1150–55.

The stylistic antecedents of these schools are difficult to pinpoint. The Saint-Denis-Chartres group has certain similarities to north French manuscript paintings associated with Marchiennes, Saint-Omer, and Anchin, but the dates of the manuscripts are not precisely known, and the problem is further complicated by the Abbot Suger's recording that the glaziers employed at Saint-Denis comprised "many masters from different regions." The strongly Romanesque character of the Le Mans Ascension window, its general composition and the particular stylization of drapery forms, is similar to such earlier manuscript paintings from western France as the illustrated Life of St. Aubin of the second half of the 12th century (Paris Bibliothèque Nationale, MS. nouv. acq. Lat. 1390). The Crucifixion window at Châlons-sur-Marne, on the other hand, has precedents in general arrangement in Ottonian

manuscript painting and is also closely related in style and composition to contemporary metal work of the Meuse valley. The similarities between the two are so marked that it is not impossible that the artist worked in both media.

**Germany.**—There is less 12th-century glass extant in Germany than in France. The outstanding example of German glass painting of the early years of the century is the series of five prophets at Augsburg, already referred to. These figures have the monumentality of design, rigidly frontal and schematic, characteristic of Romanesque art; they are extremely impressive but rather impersonal and remote. In the second half of the century art in Northern Europe generally, and perhaps more so in Germany, was influenced by Byzantine models. An example in glass painting is the Moses and the Burning Bush window now in the Städelches Museum at Frankfurt am Main.

**England.**—England has only fragmentary remains of 12th-century glass. The nave clerestory windows at York Minster contain some reused panels from a series of narrative windows, one of which depicted the life of St. Benedict, *c.* 1140–60. Another panel, a single figure of a king from a Tree of Jesse, shows some affinity in style with the glass at Saint-Chartres and Chartres, but is probably later in date, *c.* 1190. The outstanding survival from the end of the century is the splendid series of figures representing the descent of Christ from Adam, made for the choir clerestory windows of Canterbury Cathedral *c.* 1178–1200. Their features show a new humanism and there is a sense of movement, even tension, in their bodies and draperies, comparable to contemporary English manuscript painting.

**General Trends.**—It is possible that many of the early windows were of the single figure, monumental in character like the Augsburg and Canterbury examples or the well-known Virgin and Child known as "La Belle Verrière" at Chartres, but the most important feature of the 12th century was the development of the narrative window, consisting of a series of medallions painted with pictorial subjects. This development was, so far as we know, first used extensively at Saint-Denis under the direction of Abbot Suger, 1140–44. The exigencies of narrative exposition led to the decorative arrangement of the medallions within an armature or iron framework which was itself a subject for pattern, and very skilful and intricate designs were evolved, showing a counterplay of circles, lozenges, quatrefoils, and squares with their appropriate borders and interspaces, these latter being particularly elaborate. A secondary but significant development of the second half of the century was the use of decorative pattern diapers on the groundwork adjacent to the figures. This class of design was probably more common at first in Germany than elsewhere, and an early example is in the Jesse window, *c.* 1170–80, at Frankfurt am Main (Städelches Museum). In France the earliest remaining examples are the incomplete series of scenes from the Legend of St. Matthew of the late 12th century now incorporated in the 13th-century south rose window of Notre Dame, Paris.

#### 13TH CENTURY

An enormous amount of glass remains from this century and much of it has yet to be studied in detail.

**France.**—In France, where surviving material is most extensive, the various regional schools are mostly the natural development of their immediate predecessors. There is no radical change in style or technique during the first quarter of the century. In the West the severe Romanesque style was softened and refined, as seen in the St. Vital window at Le Mans about 1200, the Saint-Martin window at Angers *c.* 1210, and the slightly later windows of Abraham, Lot, and Joseph at Poitiers. Another distinct workshop, centred at Lyons and responsible *c.* 1215–20 for the apse windows of Lyons cathedral, is characterized by a strong Byzantine influence, particularly in iconography. An important workshop in Champagne had already in the late 12th century produced the clerestory windows of Saint-Remi at Reims that foreshadowed the mature Gothic style, while later products of this atelier can be found in the clerestory windows of Reims Cathedral, *c.* 1235, and the choir clerestory windows at Troyes. In the Île-de-France and eastern France the situation is compli-

cated by the almost complete loss of the later 12th-century works. The north rose window of Laon Cathedral *c.* 1200–05 is stylistically related to the contemporary sculptures of the facade and to manuscript painting such as the Ingeborg Psalter (Musée Condé, Chantilly). The work of this atelier is extremely distinguished, with an elegance and purity of style and a knowledge of classical art which transcend most of its contemporaries. The rose window of Lausanne Cathedral (Switz.), which was made 1231–35 by a wandering Picard, Peter of Arras, is related in style and iconography to the Laon workshop.

The most extensive glazing program of the first half of the century was at Chartres Cathedral, where the years 1200–36 saw the completion of some 175 windows, a tremendous enterprise which brought together various workshops from different regions. The stylistic interactions between the different workshops resulted, particularly in the second quarter of the century, in a more general similarity of style between the various regional workshops. Contemporary with Chartres are the windows of the east end of Bourges Cathedral, *c.* 1214–35, while four windows at Sens Cathedral, pre-1225, are related in composition and ornament to Chartres and Bourges and also have certain stylistic affinities with the contemporary windows at Canterbury Cathedral.

Considerable activity was also centred in the Paris area during the second quarter of the century. The major monument of the period is the Sainte-Chapelle, Paris, 1243–48, which contains the most extensive narrative cycle ever produced in this medium; they represent the medallion window at the peak of its development. Stylistically, these windows are closely related to Parisian court art of the same date and their influence can be seen in the later windows at Le Mans, about 1254–60, and at Tours 1245/55–76.

**England.**—The only extensive remains of 13th-century glass in England are found at Canterbury Cathedral, where the 12 Theological windows were produced *c.* 1200 and the windows relating to St. Thomas Becket *c.* 1200–30. Lincoln Cathedral retains impressive fragments of a series of windows made between 1200 and 1220, but it is impossible fully to appreciate either of these series without making comparison with French work. There are important similarities between Canterbury and Sens, on the one hand, and probably between Lincoln and Paris on the other. The glaziers, however, were English with a close acquaintance with French models.

**Germanic Countries.**—Glass painting of this period in German lands, however, was comparatively uninfluenced by French models. It is more forceful in design, with agitated draperies, expressive faces, and a complicated ornamental character, particularly in the backgrounds. There were many distinct regional schools, among which Cologne was an important centre. The full-length figures of saints and the Legend of St. Kunibert window in the church of St. Kunibert at Cologne (*c.* 1220–30) have elaborate geometrical frames around the figures and scenes that are without parallel in French art. These frames are a typical feature of German work; they occur again in later work of this school in the St. Nicholas window at Büchen (Weser), *c.* 1240–50, and elsewhere. Another workshop, which produced the Jesse window at Freiburg-im-Breisgau *c.* 1225, shows a marked affinity with the slightly earlier enamel and metalwork produced by Nicholas of Verdun and his circle, while the remains of a group of windows made for the Franciscan church at Erfurt, *c.* 1230, constitute a particular group strongly indebted to Byzantine models. It appears that after the completion of the Erfurt windows, this workshop, or at least some of its members, went to Italy and produced the three windows of the apse of the Upper Basilica at Assisi between the years 1230 and 1240. The most outstanding glass of the mid-century is a related series of windows at Naumburg Cathedral, Strasbourg, and Frankfurt. The Naumburg window of Holy Knights and Virgins can be contrasted with the delicate mannered style of Parisian court art.

**General Trends.**—A significant feature of the 13th century was the development of the grisaille window, composed largely of white glass, generally painted with foliage designs and leaded into a more or less complicated geometric pattern. This class of design was employed partly as a means of introducing a larger

ENGLISH STAINED GLASS

"The Patriarch Jared." 12th century window in the south transept of Canterbury Cathedral. As in much of the mediaeval glass in England, the bare flesh is out in pink glass, while the rest of the design is a harmony of blues, pale green, white, brown and yellow, arranged in fairly broad masses.

## ENGLISH STAINED GLASS

"St. Anne Teaching the Virgin." From the east window of All Saints church, York, dated about 1440. The colouring is simple though rich in quality, a characteristic of English glass of this period. St. Anne wears a ruby cloak and bonnet and a blue gown. The Virgin's dress is white, ornamented with a pale yellow pattern, and the background of figures and canopy is blue covered with a diaper. All other parts are white with some yellow stain

MODERN STAINED GLASS

amount of light and partly because it was considerably cheaper than coloured glass. The combination of grisaille glass and coloured subject medallions, or figures, however, disrupted the monumental overall unity, which is a feature of a window composed entirely of coloured glass, by allowing the penetration of pure light. This change had an important effect on style; the painted design became more linear and refined, the scale more broken and delicate. Although the combination of grisaille and medallions or figures is not unknown in the early part of the century it is more common in the second half, particularly in France and England. Important examples occur in France at Troyes Cathedral about 1270, Saint-Radegund, Poitiers, about 1290, and Saint-Pierre, Chartres, about 1300, and in England at Stanton Harcourt (Oxfordshire) *c.* 1250, Checkley (Staffordshire) *c.* 1280–90, Merton College, Oxford, 1289–96, and the Chapter House of York Minster, *c.* 1290–1300.

The movement toward humanism, partly inspired by St. Francis of Assisi and his teaching, was accompanied by a related tendency toward naturalism discernible in the visual arts in the later 13th century. The conventional formalized foliage designs of the 12th and earlier 13th century gave place to more natural plant motives of oak, vine, and maple, and these break out of the formal patterns and coil with a more organic natural movement.

#### 14TH CENTURY

##### 1300–1380: Influence of Italian Painting on Stained Glass.

—The 14th century saw the full flowering of the Gothic style side by side with the beginnings of stylistic developments that were to culminate in the Renaissance. The new movement toward the representation of volume and spatial depth, by means of modelling and linear perspective, had its origins in Italian painting, particularly in the work of Giotto at Padua, 1300–05. That the glass painter was quickly influenced by this new style is seen, for example, in the St. Anthony window in the Lower Basilica at Assisi. North of the Alps the earliest extant manifestation of this new interest in linear perspective and modeling, based on Italian models, occurs in the chancel windows of the Habsburg expiatory church at Königsfelden (Switz.) made between 1325 and 1330. The knowledge of Italian models spread quickly and extensively and can be seen in France in the windows at Saint-Ouen, Rouen, 1325–39, and at Évreux Cathedral, *c.* 1330. In the Germanic lands it influenced the transept windows at Augsburg and the east window of Vienna Cathedral, *c.* 1340, while the earliest remaining example in English glass painting is probably the nave windows of Stanford-on-Avon (Northamptonshire) *c.* 1330–35, although it occurs earlier in manuscript painting and seal design, *c.* 1325–30.

The interest in linear perspective strongly influenced the development of canopy design. The practice of representing a figure beneath an architectural canopy was an established convention of the 13th century, particularly used in clerestory windows. In the early examples the canopy plays a comparatively unimportant part in the total design, but by the end of the 13th century, although still two-dimensional, it had become more elaborate and is an important ornamental feature of the windows of Merton College, Oxford. The introduction of linear perspective, however, brought about a radical change, and the canopy became organized as a group of miniature buildings viewed in perspective. In German and Austrian glass painting in particular the canopy work is often extremely elaborate and complex in its spatial organization; typical examples are found at Vienna Cathedral, *c.* 1340, and Erfurt, *c.* 1360–70.

The art of glass painting, however, did not respond equally to these new influences emanating from Italy. It subdivides itself into two groups of which France and England together make up one, characterized by its resistance to Italian influences resulting in a modification of their general styles. The use of linear perspective was purposefully restrained, so that the essential overall surface unity of the design was not violently upset, for the use of flat patterned diaper grounds effectively counterbalanced the suggestion of spatial effect. In the first half of the century the most important work in France is found in the choir windows of Évreux Cathedral *c.* 1330 and at Saint-Ouen, Rouen, *c.* 1325–39. The

English glaziers of this period were extremely prolific, with Oxford, Coventry, and York as important regional centres. The nave windows of York Minster were made during the period 1300–38 and are the largest single collection of this period in the country. It appears probable that some of the later glass at York, *c.* 1350–70, now distributed over the windows of the choir clerestory, was the work of an imported French glazier, probably from Rouen. A flourishing school in the West Country and Herefordshire, whose best work is found at Wells Cathedral and Eaton Bishop (Herefordshire), shows some familiarity with German work. The best French and English work, however, is distinguished by a lightness of colour and graphic refinement that is enhanced by an extensive use of yellow stain. After *c.* 1300 the geometric grisaille glass gave way to the simpler form of diamond-shaped quarries, painted with delicate trails of foliage, and leaded together to give the effect of trellis work.

The second group, which might be termed 'Germanic' as it embraces east Germany, Bohemia, and Austria, displays a much more plastic style; the colours are deeper and more saturated, the compositions are more complex, both on the surface and in depth, and the canopy designs particularly are often very complicated essays in perspective; the figures are shorter in proportion and their volume more accentuated. It is brusque, almost harsh, contrasting strongly with the elegance of French and English work. All these traits can be seen, for example, in the panels from Strassengel, near Graz, Aus., *c.* 1350 (Victoria and Albert Museum, London), the earlier windows at St. Maria-am-Gestade, Vienna, *c.* 1350–60, at Erfurt, *c.* 1360–70, and the window from the Herzogenkapella in Vienna Cathedral, *c.* 1380. A particular trait of this Germanic group, of which Erfurt is a good example, is a tendency to extend a single composition across the main lights of a window, ignoring the natural divisions of the stonework. The reason for this is partly architectural: the windows are comparatively much narrower and taller than French or English windows.

**1380–1430: The International Style.**—The arts of this period which are conveniently grouped together under the title of "The International Style" belong essentially to an era of court art inspired by the patronage of kings and the nobility and the higher orders of ecclesiastics. Surviving monuments are extensive and interactions between the various centres of patronage, complicated by family alliances and the exchange of works of art and artists, are particularly complex. The various national and regional styles can still be distinguished but there is a general tendency toward a mannered, extremely sophisticated elegance of style, sometimes verging on the precious, combined with an interest in portrait realism.

The glass painting of this period is of high quality. The most significant examples in France are the "Royal" windows at Évreux, given by Pierre de Mortain *c.* 1395, and the window of Bishop Guillaume de Cantiers. At Bourges there are tantalizing fragments from the Sainte-Chapelle built for Jean, duc de Berry, *c.* 1405, and also the windows presented to the cathedral there by the families of Trousseau and Aligret, *c.* 1414. In England the major examples of this period are the windows of the chapel of William of Wykeham's college at Winchester painted about 1393 by Master Thomas of Oxford, and the great East Window of York Minster. This was made between 1405 and 1408 by John Thornton of Coventry and must be considered as one of the outstanding works of art of the Middle Ages.

In Germany and Austria the International Style brought about a softening and refining of the "plastic style" of the earlier part of the century. In Austria an important atelier associated with the court produced the window given by Duke Albert III to the church of St. Erhard in der Breitenau *c.* 1386–95, and later the series of windows at Viktring *c.* 1400 and for the Freisingerkapella at Klosterneuburg *c.* 1410. Germany contains a large amount of work of this period. At Erfurt the window given by Johann von Tiefengruben *c.* 1400, with its lighter tones and more refined pictorial style, should be compared with the earlier windows there. The series of windows at Rothenburg, which were probably made about 1400, should be noted, together with the cycle of windows, probably painted by Lucas Moser, for the Bessererkapelle at Ulm

Minster, c. 1420-30. The latter show an astonishingly refined technique.

#### 15TH AND 16TH CENTURIES

##### **Decline of Stained Glass as an Independent Art Form.**—

The period 1430-1550 saw not only the decline of the Gothic style and the establishment of the new Renaissance style but also the beginning of the transformation of the art of glass painting from a significant means of artistic expression into a hybrid art form: the translucent reflection of a panel or mural painting.

The International Style continued to influence glass painting during the first half of the 15th century, but to a lesser degree. Its mannered elegance and extravagant costumes can still be seen in the two rose windows at Le Mans Cathedral, c. 1440, although technically this work is somewhat coarse, and also the rose windows at Angers Cathedral of 1441-42. In England this aesthetic is continued in the east window of Great Malvern Priory (Worcestershire), about 1423-39, the chapel windows of All Souls College, Oxford, 1441-47, and in the windows made by John Prudde, the king's glazier, for the Beauchamp Chapel of St. Mary's, Warwick, which were commissioned in 1447. The Germanic lands provide many examples, particularly the window from St. Lambrecht, after 1424, now in the museum at Graz, Aus., and the charming St. Katherine window at Sélestat, Fr., c. 1425-1450.

**Influence of Flemish and Italian Realism.**—There were, however, important new influences affecting the styles of glass painting. In northern Europe during the first half of the 15th century a flourishing school of painting emerged in Flanders. Although the origin of the Flemish style is partly to be found in the International Style of 1390-1400, it developed, as can be seen in the paintings of Jan Van Eyck, a more realistic manner of representation and a detailed awareness of actuality that is almost the antithesis of the mannered sophistication and the essentially unrealistic world of the International Gothic. In Italian sculpture and painting also a new realism is found, particularly in the later works of Ghiberti (1378-1455) and Donatello (c. 1386-1466) and their new developments in the use of perspective to create the illusion of reality.

It was impossible for the glass painter to participate fully in the new realism. Glass is a translucent material; the passage of light through it is alone sufficient to create a feeling of unreality. Furthermore, although the panel or mural painter could use the new discoveries of perspective to heighten the sense of reality, the glass painter had to compromise with the presence of the leading line which emphasizes the surface plane. This creates a tension and a sense of ambiguity between the actual surface and the illusion of depth. Attempts were made to resolve the problems, but with little success: one result was that the leading line became partly divorced from the design instead of being an integrated part of it. The increasing use, from the mid-16th century onward, of vitreous enamel pigments hastened this process.

**Importance of Flemish Glaziers.**—The period 1450-1550 saw no decline in demand. One of the most productive and influential areas at this time was Flanders. The six windows of the church of St. Gommaire at Lier, c. 1475-1500, and the Virgin window at Anderlecht, c. 1482, although very restored, have original portions of excellent quality and close affinity with contemporary painting. The trading and political links between Flanders and England in the second half of the 15th century encouraged the influx of Flemish works of art and artists into England. A number of Flemish glaziers established themselves in Southwark, London, and some even assumed English names. The early 16th century was marked by a series of disputes between the London Guild of Glaziers and the foreigners. The latter were particularly patronized by the Court and the more wealthy merchants. The two outstanding monuments of this imported style are the windows of Fairford church (Gloucestershire), c. 1480, and the King's College Chapel, Cambridge, 1515-31. Many of the windows at King's were probably designed by the painter and engraver Dirck Vellert of Antwerp (working 1485-1534).

The spread of the new realism can be traced in French glass painting. The interactions with Flemish glaziers can be seen, for

example, in the realism of the windows from the duke of Burgundy's chapel at Dijon, which are the work of Flemish glaziers, c. 1430-40, now in the Victoria and Albert Museum, London, and also the Jacques Coeur window at Bourges Cathedral, c. 1450 which is markedly Flemish in style. The native glaziers were extremely prolific at this time, and Normandy and particularly the city of Rouen contain an incomparable display of windows produced by a large number of distinctive workshops. The outstanding figures of the first part of the 16th century were Arnould of Nijmegen (c. 1470-c. 1540) and the Le Prince family at Beauvais. Arnould of Nijmegen worked in both Flanders and France. His most important works are at Tournai Cathedral, 1490-1500, and the Jesse window at Saint-Godard Church, Rouen, of 1506, which is one of the most impressive monuments of glass painting. The works by the Le Prince family are equally impressive, particularly the Tree of Jesse at Saint-Étienne, Beauvais, c. 1522-25.

**Germany and Italy and Spain.**—In Germany the later 15th century is dominated by the prolific activity of Peter Hemmel von Andlau and his workshop, active 1430-1500. Typical examples of his work are found in St. Wilhelm's Church, Strasbourg, c. 1470-80. In Italy the period is mainly associated with the name of Guglielmo de Marcillat (1467-1529), a Frenchman whose works display an outstanding mastery of technique. His finest windows are at Arezzo Cathedral and there is a very typical example from the cathedral of Cortona, dated 1516, in the Victoria and Albert Museum. The building of Milan Cathedral caused an important school of glass painting to develop there, and the work of Conrad Munch, a German from Cologne, and Nicolo da Varallo carried out during the second half of the 15th century is of particular importance. The Milan school continued in full activity during the 16th and 17th centuries. In Spain, especially at Seville, León, and Avila, there are some magnificent 16th century windows; they are in all cases the work of imported Flemish glass painters.

The full flowering of the Renaissance style in Italy and the intense interest in classical art that it stimulated resulted, c. 1500, in a profusion of ornamental details, borrowed from the formal language of classical art, in contemporary window designs. In addition the glaziers at this time often drew inspiration from contemporary engravings, particularly those of Albrecht Dürer (1471-1528).

#### 17TH AND 18TH CENTURIES

**Dominance of the Painted Technique.**—Political disturbances and the devastation of Lorraine with the destruction in 1636 of the important glass works there resulted in some scarcity of pot-metal glass, but the use of vitreous enamel colours was already dominating the technique of glass painting. In the windows at Gouda, Holland, painted by the brothers Dirk and Waiter Crabeth at the end of the 16th century, and in the works of Abraham and Bernard Van Linge, made between 1620 and 1640, the realization of the window as a translucent canvas painting is complete. Abraham Van Linge's windows painted 1630-40 for Christ Church Cathedral, Oxford, are an excellent example of the destruction of the lead line as an integral part of the design. The leading simply holds together the square sheets of glass: the effect is the same as looking at a picture set behind a rectangular grid. This type of design was continued by English artists such as Henry Gyles (1645-1709), and the Price and Peckitt families, all of York, and by artists like Francis Eginton (1737-1805) and James Pearson (d. 1805). At its best the work of these centuries has a certain charm with a delicacy of painting and often some technical expertise.

**Domestic Glass.**—The most interesting work of the period was the extensive production of small subject roundels and heraldic panels, particularly fashionable for use in domestic windows, made in vast quantities in Flanders and Switzerland.

#### 19TH AND 20TH CENTURIES

**Gothic Revival.**—The Gothic revival that came as an offspring of the Romantic movement of the late 18th and early 19th centuries represents the beginning of a revitalization of glass painting. The revival of interest in Gothic art stimulated an interest in both

the technique and history of medieval glass painting. The pioneer figures in this field were E. Viollet-Le-Duc (1814–79) in France and Charles Winston (1814–65) in England. Winston was a lawyer and antiquarian who associated with various London glaziers and, with the technical help of Messrs. James Powell and Sons, brought about a considerable improvement in the technical quality of pot-metal glass. The experiments were continued by W. E. Chance, who first successfully produced "antique" glass in 1863.

In the first half of the 19th century the styles and methods of the early Gothic period were reconstructed, but without much aesthetic appreciation of medieval art. Much of the work was stereotyped and mass produced, particularly in Germany, and varied considerably in technical quality. The latter part of the century is dominated in England by Edward Burne-Jones (1833–98) and William Morris (1834–96). Burne-Jones provided the designs and Morris adapted them to the medium of stained glass. In windows by them the leading work is restored as an integral part of the design, as seen, for example, in the windows of Birmingham Cathedral of 1897. Although the style and sentiment of 19th-century work is not much in favour today, the period had great historical significance in the revival of the actual technique of making stained glass.

**Modern Trends.**—The advent of "modern art" created new opportunities for the art of stained glass. Contemporary achievements in structural engineering allow for the maximum use of glass as a material, and the abstract and semi-abstract styles of modern art are particularly well suited for expression in this medium. The exploration of these possibilities has interested major artists, and stained glass is being restored as a monumental art occupying a significant and complementary position within its architectural setting.

Although the bulk of this activity belongs to the period after World War II, earlier experiments in France and Germany suggested the range of possibilities that were being opened up. In France the church of Le Raincy (Seine-et-Oise), with abstract window designs of 1922 by Maurice Denis, had great technical significance for the future in its combination of glass and concrete, while in Germany the work of Jan Thorn-Prikker and Karl Schmidt-Rottluff gave to the symbols and images of Christianity an intensity and realism for which there had been no parallel in glass this side of the Renaissance.

After 1946 there was an amazing burst of activity. Technical freedom was greater than ever before, and the experimental nature of much contemporary work, as well as the differing aims of the various artists and architects involved, make it difficult to generalize. On the whole, however, there was a marked tendency to abandon leading in favour of a concrete setting, and designs were either abstract or semi-abstract. Abstract compositions, which explore the possibilities of pure light and colour, include Matisse's "Life" of 1953 at New York, and the works of Jean Bazaine at the Châteaux de la Chaux of 1954 and J. L. Perrot's window at the church of Sainte-Jeanne d'Arc at Belfort (both in France). In Ireland work of great distinction was carried out by Evie Hone, whose semi-abstract windows can also be seen in England; e.g., at Eton College (1952). Traditional iconography reinterpreted in a modern idiom, with a depth of spirituality and sureness of technique that invite comparison with the greatest works of medieval art, is also to be found in Fernand Léger's window of the Marriage at Cana at Courfaivre (Switz.) of 1954 and the St. Dominic window designed by Georges Braque at Varengeville (Seine-Maritime, France). Among the outstanding achievements of the 1960s were Marc Chagall's magnificent series of windows for the synagogue of the Medical Centre at Jerusalem of 1961 and John Piper's Baptistery window at Coventry Cathedral of 1962.

**STAINES**, an urban district formerly in Middlesex, Eng., which under the London Government Act 1963 became part of Surrey on April 1, 1965 (see LONDON). It is on the Thames, 18 mi. (29 km.) SW of Charing Cross. Pop. (1961) 49,838. A Roman station was situated there, on the main road from London, and this Thames crossing was one of the earliest bridges. The old bridge, by George Rennie, was opened in 1832; a new one in nearby Egham (1961) carries a bypass. The London Mark Stone was placed there in 1285 to mark the western limit of the City of London's jurisdiction over the Thames. An annual fair granted in 1228 was abolished in 1895. The urban district includes Ashford, Laleham, and Stanwell; it is mainly residential, but there are engineering works and some factories.

**STAINLESS STEEL.** Stainless steel basically is an alloy of chromium and iron containing more than 10% chromium. When chromium is added to iron in such quantities, it imparts throughout the entire body of the metal remarkable resistance to corrosion and heat. Other elements may be added to the iron-chromium combination to obtain steels with special characteristics. The most important of these is nickel, which is used to produce 18–8 (that is, 18% chromium, 8% nickel, balance iron). Other useful additions are niobium, manganese, molybdenum, phosphorus, selenium, silicon, sulfur, titanium and zirconium, all of which result in modifications for special service or fabrication. As is true of many scientific discoveries no single nation can claim full credit for the development of stainless steel. Between 1903 and 1912 Harry Brearley of England, F. M. Becket of the United States and Benno Strauss and Eduard Maurer of Germany shared in its initial development.

Selected scrap which contains only those elements desired in the finished product usually makes up the bulk of the furnace charge used for producing stainless steel. If alloy scrap is not available, clean open-hearth scrap may be used, but more alloy is required to meet specifications. Pig iron containing 4% carbon, anthracite, or other carbonaceous material may be employed when a high-carbon melt is desired. Lime, silica, crushed coke, aluminum, silicon, fluorspar and iron ore are materials used for slag constituents and for controlling the composition of the metal bath. Because of the high temperatures and precise chemical control required, all stainless steel is produced in the electric furnace. Oxidizing and reducing slags may be used successively in the same heat, depending on the composition of the charge and the analysis of the product. Sulfur is removed from the metal with a reducing slag containing more than 2% calcium carbide, and silicon, phosphorus, manganese, chromium and carbon, with an oxidizing slag. However, carbon presents a problem in the presence of

chromium, because of the chemical affinity chromium has for carbon. Carbon may be absorbed by the metal at the same time chromium is being oxidized and going into the slag. To oxidize carbon in a charge containing a high percentage of stainless steel scrap requires an excess of oxygen and extremely high temperatures (more than 3,200° F. [1,760° C.]). Oxygen supplied through a lance into the molten bath is used to a large extent to replace iron ore as a source of this element. Considerable chromium is oxidized along with the carbon, and the resultant slag will contain a high percentage of chromium oxide. Chromium oxide may be reduced and returned to the metal by the addition of lime and crushed ferrosilicon.

The stainless steels may be grouped according to chemical composition and response to heat treatment as follows: (1) ferritic steels, nonhardenable steels containing 15% to 30% chromium and with low carbon contents (from 0.08% to 0.20%), (2) martensitic steels, hardenable (by quenching) steels containing 10% to 18% chromium with varying carbon contents (0.08% to 1.10%), and (3) austenitic steel containing 16% to 26% chromium and 6% to 22% nickel, which is hardenable without quenching.

**Ferritic Stainless Steels** are better than the martensitic type and as good as the austenitic type in resistance to corrosion. However, because of their lower ductility they are not used to replace the austenitic type. Ferritic steels are magnetic and can be hot- and cold-worked but usually undergo excessive grain growth during prolonged exposure at elevated temperatures. They have lower high-temperature strength than the other two types and may develop brittleness after electric-arc, resistance or gas welding. Machinability is good and can be improved by adding sulfur or selenium. There is no tendency toward intergranular corrosion.

Ferritic stainless steel, American Iron and Steel Institute (A.I.S.I.) type 430, is widely used for automotive and architectural trim.

**Martensitic Stainless Steels** are magnetic; they can be cold-worked without difficulty, especially when the carbon content is low; show satisfactory resistance upon exposure to weather, water and some chemicals; can be machined satisfactorily; have toughness; and are easily forged or otherwise hot-worked. The corrosion resistance is usually increased by hardening, which is accomplished by quenching. Welds made by the electric-arc, resistance or gas methods contain some martensite after cooling in air. A.I.S.I. type 410 is the most widely used of the martensitic grades. In sheet or strip form, this grade is used extensively in the oil industry for bubble trays, bubble caps and liners.

**Austenitic Stainless Steels** are not magnetic unless severely cold-worked. They can be hot-worked, and cold-worked if proper allowance is made for their rapid work hardening. Except for surface hardening, their alloys cannot be hardened by heat treatment. They are extremely shock-resistant and difficult to machine unless they contain sulfur or selenium. These steels can be welded with difficulty, and, if the welding operation is controlled properly, the resistance to corrosion is not impaired. These steels have the best high-temperature strength and resistance to scaling of the stainless steels. However, they are subject to intergranular corrosion at temperatures between 800° and 1,600° F. (425° to 870° C.) unless the structure is stabilized to prevent the presence of carbides at or near grain boundaries which are vulnerable to corrosion. Stabilization may be done by the addition of titanium (4 to 6 times the carbon content) or niobium (8 to 10 times the carbon content), which combine with carbon and prevent the formation of chromium carbides. The corrosion resistance of the austenitic stainless steels is usually better than that of the other two groups.

A.I.S.I. type 304, a companion grade to types 301 and 302 with somewhat lower carbon (0.08% maximum), is the most widely used of austenitic grades. It is well suited to withstand severe forms of corrosion encountered in the paper and chemical industries. The austenitic grades most resistant to oxidation are types 309 and 310, which are high in nickel and chromium. These steels resist scaling up to 2,100° F. (1,150° C.) and consequently are used for furnace parts and heat exchangers.

The heat treatment of stainless steels may be carried out with

any conventional type of electric, gas-fired, oil-fired, salt-bath or induction furnace. Although all stainless steels are highly resistant to oxidation, they may be expected to scale slightly at high heat-treating temperatures. The scale formed on the stainless steels is tenacious and relatively impervious and, consequently, is more difficult to remove than scale on ordinary carbon steel. Two basic methods are used: mechanical, such as sandblasting and tumbling; and chemical, such as pickling in acid solutions.

An important development in the stainless steel industry was the increased use of austenitic stainless steels containing manganese instead of nickel as a major alloying element. These were substituted for A.I.S.I. type 301 (18% Cr, 8% Ni), because of the current shortage of nickel. Manganese, like nickel, has the property of producing an austenitic structure in steel, although it takes twice as much to do it. Steel containing 15% Cr minimum, 16.5% Mn, 0.10% carbon maximum, and 1% Ni as a substitute for type 301 stainless is being used.

**STAIR, JAMES DALRYMPLE**, 1st Viscount of (1619–1695), Scottish lawyer and statesman, president of the Court of Session from 1671 to 1681 and from 1689 to 1695, was born in May 1619 at Drummurichie, in Ayrshire. Regent of the University of Glasgow (1641–47), he was admitted to the bar in Edinburgh in February 1648. He was secretary of the commissions sent by the Scottish Parliament to treat with Charles II at The Hague (1649) and at Breda (1650), and during the latter negotiations the king decided, on learning of the failure of the marquess of Montrose's expedition in Scotland (May 1650), to accept the Covenanters whereby he could return to Scotland as king. Dalrymple met him on his landing in Moray in June. He refused in 1654 to take the oath of allegiance to the Commonwealth, but in 1657, on the recommendation of George Monck, he was appointed a commissioner of justice in Scotland.

After the restoration of Charles II in 1660, he was received with favour by the king, was knighted, and in February 1661 was made a judge in the Court of Session as Lord Stair. He refused in 1664 to take the declaration that the National Covenant and the Solemn League and Covenant were unlawful oaths and resigned, but the king allowed him to take the declaration under an implied reservation. In 1669 a family disaster took place, the exact facts of which will probably never be known. His daughter Janet, who had been betrothed to Lord Rutherford, was married to David Dunbar the Younger, of Baldoon, and some tragic event occurred on the wedding night from which she soon died. Sir Walter Scott took the plot of *The Bride of Lammermoor* from the incident.

Lord Stair was appointed president of the Court of Session in January 1671. He was member of Parliament for Wigtownshire (1672–74, 1678, 1681) and for Ayrshire (1689–90). He refused to sign a test or oath renouncing the Covenants in 1681 and was replaced as president by Sir George Gordon. He now published his great legal work, *The Institutions of the Law of Scotland* (1681), with a dedication to the king. In October 1682 he went to Holland and lived at Leiden. Whilst there he published in 1681 at Edinburgh the *Decisions of the Court of Session Between 1661 and 1671*, and in 1686 at Leiden a small treatise on natural science, *Physiologia Nova Experimentalis*. In his absence a prosecution for treason (1685) was raised against him and others of the exile by Sir George Mackenzie, the law advocate, but the charge was dropped when his son, Sir John, the master of Stair, who had made

his peace with James II and VII, was appointed lord advocate in 1687. Lord Stair returned to England with William of Orange at the Revolution in 1688. He was again made president of the Court of Session in November 1689 and was created viscount of Stair in April 1690. The massacre of the MacDonalds of Glencoe (Feb. 13, 1692), for which his son, the master of Stair, was largely responsible, naturally reflected on him. Stair died in Edinburgh in November 1695.

See J. M. Graham, *Annals and Correspondence of the Viscount . . . of Stair*, 2 vol. (1875); A. J. G. Mackay, *Memoir of Sir James Dalrymple* (1873). (G. S. P.)

**STAIR**, a series of steps arranged one above the other, occasionally varied by platforms known as landings. The total height of a stair is the rise, the total horizontal distance between the top and bottom steps is the run. A series of steps without a landing is called a flight. The horizontal surface of a step is called its tread, and the vertical front its riser. The projection of the tread beyond the face of the riser is termed a nosing. Staircase is a term for stairs accompanied by walls.

### HISTORY

It is uncertain what is the oldest stair in existence. On the sacred road up the mountain of T'ai Shan, in Shantung, China, there are many great flights of ancient granite steps. The earliest staircases seem to have been built with walls on both sides, as in Egyptian pylons which date from the 2nd millennium B.C. Contemporary models of houses, dating back to the middle kingdom, show a staircase leading up the side of a court to a roof terrace, with continuous wall below.

The origin of such stairs may have been earlier structures in wood, or even ladders cut out of logs. Egyptians may have used the self-supporting staircase in which each step is supported at its front by the step below and prevented from turning by having its end built solidly into a wall. The Assyrian ziggurat (q.v.) of the 9th or 8th century B.C. was often adorned with massive stairs; and the palace terrace at Persepolis has a double flight of steps, of great beauty, which shows the skill of the Persians in the 6th century B.C.

Farther west, stairs played an important part in the Cretan palaces, as in the palaces at Knossos and Phaistos (both c. 1500 B.C.). In Hellenic Greece the monumental stair was of less importance, due to the Greek love of informal and picturesque approaches. Thus in Athens the Propylaea of the Acropolis was probably entered by a winding path and the present great flight of stairs, dating from the Roman period, is not part of the original design. Interior staircases were common but unimportant; they were placed in out-of-the-way corners, and often built of wood. In the post-Alexandrian period there developed a new love of monumental grandeur, largely Asian in origin, which produced such magnificent stairs as those of the altar of Zeus at Pergamon (180 B.C.).

A similar monumental sense distinguished Roman stairs. Those of the propylaea at Baalbek (time of Hadrian), over 100 ft. wide, are typical, and again and again stairs are made essential parts of great architectural conceptions, as in the Temple of the Sun on the Quirinal hill at Rome, built by Aurelian (A.D. 273), some of the steps of which were taken, in 1348, to build the famous stairs of the Aracoeli on the Capitoline hill at Rome. Many of the apartment houses indicated on the marble plan of Rome (c. A.D. 205), now in the Palazzo dei Conservatori at Rome, seem to have had stair towers built in the centre of a courtyard. The Colosseum at Rome (completed A.D. 80) has elaborate and practical entrance and exit stairs, by which the crowds could be readily handled. These, in general, are supported and roofed by sloping vaults. Similar staircases were common in the theatres.

Merely inclined planes lead up within enormous buttresses at the ends of the narthex of Hagia Sophia (532) at Constantinople, so giving access to the galleries. In St. George at Salonika (late 5th century) a spiral staircase surrounds an open well. In the early Romanesque there is a growing use of the spiral staircase. To this development the great thickness of Romanesque walls and buttresses was particularly congenial, as it allowed the staircases

to be built in solid masonry. Not only was the open circular well used, but the solid newel, in which each step had cut upon it a cylindrical form to act as part of the newel. This type of spiral staircase is still in use.

Although during the European middle ages stairs were used more for utilitarian than aesthetic purposes, where they were necessary they received adequate treatment, usually more direct and informal and more picturesque than those of the Roman tradition. Thus at Le Puy en Velay, in France, the 11th-century cathedral, which was built on a hilltop, is approached by a magnificent stair that provides a superb foreground to the polychrome façade. The steps that mount up to and past the apse of the 14th-century cathedral at Erfurt, in Germany, show the direct and beautiful relationship between the building itself and the stairs which is characteristic of the best Gothic usage.

The Gothic spiral staircase was cut with the utmost cleverness. Such circular staircases as those which lead up in the traceried turrets of the spire of Strasbourg cathedral in Alsace (1435) are miracles of daring design and delicate execution. The spiral staircase at the abbey church at St. Gilles, which is known as Vis St. Gilles, is of hewn stone built round a circular newel and covered with a semicircular rising vault.

The late Gothic period also produced a great number of beautiful interior staircases, like the "Stair of the Library" in Rouen cathedral (1477-79), which show that the possibilities of the staircase with straight runs were at last being realized. Of rich interior spiral staircases, the early 16th-century staircase leading to the organ in St. Maclou, in Rouen, and the contemporary staircase to the jube (q.v.), or rood loft, of St. Étienne du Mont in Paris (in which a certain amount of Renaissance feeling is present) are noteworthy. In the larger houses the lack of communicating passages led to many staircases. Thus in the house of Jacques Coeur at Bourges (c. 1450) there are eight separate spiral staircases, whose exterior treatment, in rich, traceried towers, furnishes a great deal of the picturesqueness and varied beauty of such a building.

In France the spiral staircase added by Francis I to the château at Blois (1515-24) and the double circular staircase of the château of Chambord (begun 1519) are remarkable. The early Renaissance, however, produced its most remarkable results in the richly ornamented wooden staircases of Tudor and Jacobean houses of England. The usual arrangement was to have the staircase divided into comparatively short flights, at right angles to each other, around a central open well. The heavy newels at the corners were finished with unlike finials at the top and carved drops at the bottom; the railing consisted of a large rail supported either by miniature arcades or square balusters, whose moldings were often sloped to follow the stairs; and the whole was covered with intricate surface ornament of strapwork. The staircase at Hatfield house (1611) is typical.

The early Renaissance staircases of Spanish palaces are in most cases placed in one corner of the courtyard and run up between walls to a landing with a return flight that opens out onto the upper-floor gallery. The walls, and sometimes even the treads and risers, are often cased in brilliant faience tiles. Even in staircases of more Italian type, with balusters, the richness of wall surface remains, as in the staircase of the hospital of Santa Cruz at Toledo (1504-14), by E. de Egas. The climax of Spanish Renaissance monumental stair design is reached in the Escalera Dorada at Burgos cathedral (1519), by D. de Siloe, with its exquisite metal railing.

The Renaissance produced a recrudescence of the tradition of Roman formality in stair design. Despite such tours de force as G. Vignola's spiral stair in the palace at Caprarola (c. 1550), the general practice was to have important staircases run up in a straight flight, sometimes varied by landings, and sometimes with changes in direction between walls often crowned with a slanting vault. The most perfect developments of this type were made chiefly during the baroque period. The magnificence of the huge interior flights of the Genoese palaces (e.g., the University, 1623, by B. Bianco) is famous. The so-called Spanish stairs at Rome in the Piazza di Spagna (1723-26), by F. de Sanctis, those of the

Campidoglio, at Rome (begun 1547), by Michelangelo, and the infinitely varied terrace stairs of the Italian villas should also be mentioned. The inspiration of these Italian baroque stairs was felt throughout Europe and is largely the foundation of stair design in modern city and garden planning. Thus the enormous stairs of the gardens of Versailles (1667-88), by A. Le Nôtre, owe much to the Italian precedent, and were themselves imitated widely all over Europe.

Classicism combined with the baroque to give a new trend to staircase design throughout Europe. In France a gorgeous series of staircases was produced, of which the Escalier des Princes of Versailles is typical. The reaction to the lightness and gaiety of the Louis XV period (see LOUIS STYLES) led to the development of many gracious and inviting house staircases of the type known as self-supporting, full of sweeping curves and with railings frequently of metal. In the Louis XVI period the new, popular classicism restrained the exuberance of the earlier staircases but retained their graciousness and lightness; of these, one of the loveliest is that of the Petit Trianon at Versailles (1766), by A. J. Gabriel, with a beautiful iron railing. Meanwhile, the classic trend had expressed itself in England by the substitution of open-string for closed-string stairs, that is, with the balusters coming down to the top of each tread rather than being supported on a slanting member, or string, which received the ends of the treads. This at once made for a more interesting treatment at the ends of the steps and led, eventually, to the development of the bracketed step end, in which scrolls and leafage of great richness were carved under the end of each riser. Moreover, the fact that English

stairs were largely of wood inspired the design of turned balusters and newels of great variety.

During the last half of the 18th century a growing trend toward lightness and delicacy of design led to the substitution of plain, tapered shafts in place of elaborate balusters, and the use of stairs rising in continuing curves instead of straight flights and landings. The same development took place during the 18th century in the colonial work of North America.

Thus certain of the earliest houses, like the Capen house at

Topsfield, Mass., 1683, have closed strings and heavy newels of Jacobean type, while the Lee mansion at Marblehead, Mass., 1768, has a magnificent open-string staircase, whose steps have paneled and scrolled ends and whose twisted balusters are as rich as any contemporary work in England. The curved staircase of the Valentine museum at Richmond, Va., 1812, is typical of the later delicacy.

During the middle and the third quarter of the 19th century staircase design reached its lowest ebb, not only in England and France, but throughout Europe, except in the case of those monumental and official buildings in Europe whose design never fell a victim to the current taste. Closed strings, balusters and newels of gargantuan proportions, and bulbous and meaningless elaboration again became the fashion. Yet one of the most gorgeous and effective staircases in the world dates from this period, that of the Paris Opéra (1861-75), by Charles Garnier.

Two elements have vastly affected modern staircase design, steel and reinforced concrete. The use of steel has led to simple plans of straight runs, and railings delicate and straightforward in design. Reinforced concrete, on the other hand, is a material so flexible that the most daring curves and fantastic sweeps become structurally sound. The masters of contemporary architecture have given new vitality to staircase design with such superb examples as the glass enclosed circular staircase of the Werkbund Exposition building at Cologne, Ger. (W. Gropius and A. Meyer), the interior stair of Frank Lloyd Wright's own house at Spring Green, Wis., and "Les Terrasses" at Garches, France, by Le Corbusier.

Contemporary architecture has largely de-emphasized the monumental stair and the monumental building. Most frequently entrances are effected at ground level. Emphasis has been placed on the small, light, open, free-standing stair (Gropius house, Lincoln, Mass., W. Gropius, 1939); on the intimate and picturesque (Wellesley college art centre, Mass., P. Rudolph, 1957); and on the short-run formalized axial solution (Architecture building, Illinois Institute of Technology, Chicago, Mies van der Rohe, 1955). There is, perhaps, some evidence that contemporary architects have given exterior stairs something less than adequate study.

In the orient the stairs leading down to the river at Benares, in India, of various dates, combine monumentality and picturesque-ness; a similar skill is shown in the design of large numbers of temple and palace steps throughout the peninsula. Farther east the ruins of Angkor use wide flights of steps with magnificent effect in connecting the various levels of the terraced group. The Chinese have always been superb stair designers and builders, and there is hardly a temple or large house or palace which does not owe some of its effect to its stairs, either monumental and formal, like those of the Forbidden City or the Temple of Heaven, both in Peking, or winding and informal, as in Chinese garden design. Many of the temple stairs have, in the centre, an inclined plane running the entire height of the rise, richly carved with the symbolic dragon—the so-called spirit stairs by which the beneficent powers are supposed to enter. In Japan the tradition is much more informal, but the hilly nature of the country makes stairs an important feature of almost every temple layout.

## STRUCTURAL DESIGN

Long use has demonstrated that certain proportions of riser and tread are safe and easy. For interior stairs twice the height of the riser, plus the length of the tread, should be 23, all dimensions being in inches. A variant is that the sum of riser and tread should be between 17 and 17½ in.; a third rule specifies that the product of riser and tread, in inches, should be not less than 70 nor more than 75. In general, English usage advocates a slightly lower rise for a given tread than U.S. usage, while in Europe the rise is frequently greater. For exterior stairs, the general usage is to keep the riser below 6 in. and the tread above 12.

**Stone and Marble Staircases.**—Modern stone and marble staircases are of two main types. In the first the actual exposed treads and risers form, themselves, the structural elements. In the other type the treads and risers are supported upon a separate structural base which may consist of a masonry vault, a steel framework or, a reinforced concrete slab. In the first class, in which the steps themselves are structural, the staircase is usually built into a wall at one side. Each step rests for a small distance upon the step below and is built into the wall for a distance sufficient to make the weight of the wall above prevent it from turning. The undersides of the steps, where exposed, are frequently cut to form an inclined surface, following the slope of the stairs, and may be decorated with paneling or carving or other ornament. This type of stair can be used both for straight and curved runs, and is particularly applicable to monumental entrance halls, where the stair, in a triple run with two landings, or in a continuous, curved sweep, fills a recess opposite the door. In such staircases the railing is usually of metal with the uprights securely doveled into the ends of the steps. Stairs somewhat similar can be built with the ends of the steps built into the walls on both sides, where a monumental run rises between two walls.

**Wooden Staircases.**—These can be divided into two classes, closed- and open-string stairs. In both, the essential support is given by rough timbers called carriages, which follow the slope of the stairs and are cut roughly to the shape of the underside of the steps.

In the case of closed-string staircases both sides of the staircase are finished by a sloping, straight-sided plank, approximately an inch and a half thick, on the inner faces of which grooves are cut, whose upper and outer faces exactly fit the top and side of the tread and riser; the under- and inner sides are, however, sloped, so that wedges may be driven in to force the tread and riser boards into position and hold them with perfect rigidity. Similar wedges are driven in between the rough carriages and the undersides of treads and risers. To give additional strength, the treads and risers are themselves rebated together, so that a small, projecting strip of the tread fits into a groove in the bottom of the riser, and a similar strip on the top of the riser fits into a groove on the bottom of the tread. The

projecting portion of the tread is molded and an additional small cover mold placed below to cover the joint.

In the open-string staircase the strings at the end are cut to the shape of the steps, and the vertical cuts are usually mitred at 45°, so that the ends of the risers, also mitred, may form with them an invisible joint. In the ends of the treads dovetailed sockets are left to receive the dovetailed ends of the balusters; a molding, exactly similar to the nosing, is then applied across the end of the step and covers the bottom of the balusters. At times, bracketed and carved pieces are mitred at the ends of the risers and applied over the face of the string. It is this type of staircase that was the rule during the Georgian period in England and in the developed American colonial and early republic work. Where an open-string stair is built against a wall, it is usually finished at the wall end by a closed or housed string, similar to that described, forming a baseboard for the wall.

The structural strength for a wooden staircase is usually furnished by framing a heavy member, called a header, at the top and bottom of every run; to these headers the rough carriages are spiked, and the newels, if they exist, firmly fastened. The newels themselves are designed to receive the finished stair strings, and also the finished string member that is occasionally used at the edges of a floor in the stair-well opening. In modern staircases of this type additional strength is obtained by inserting iron or steel bands into the handrail; occasional balusters may be of steel, well fastened to the string.

**Steel Staircases.**—These have become almost universal in modern fireproof buildings of all types, except where unusual monumental effect is desired. The design of steel staircases is largely standardized. They consist of a steel string on each side, which takes the form of a plate or channel of sufficient rigidity to carry the weight.

Iron spiral staircases are usually formed of cast-iron members, each of which forms a tread and riser and has, at its inner end, a collar arranged to slip over a vertical pipe or cylindrical bar forming the central newel. Such spiral staircases are rigid independently of any wall, and are frequently used in open spaces, such as those existing in power houses, gymnasiums and the like. Reinforced concrete, sometimes finished as artificial stone, is used for stairs and permits of infinite variety of form.

**Moving Staircases.**—In many places where continuous transit between floors is necessary, as in large shops, underground railway stations and the like, moving stairs, sometimes known as escalators, are much used. (See ESCALATOR.)

**Legal Regulation.**—As stairs form one of the most necessary methods of exit from a building, their design has formed one of the most important portions of the building legislation of modern municipalities, especially in the case of public, commercial, industrial and educational buildings. Thus, in addition to the universal requirements for structural solidity, the attempt is generally made to furnish at least two stair exits to any large, enclosed, upper-floor area; and where fire risk and the danger of panic are unusually great, as in the case of theatres, to demand sufficient stairs to allow the building to be emptied in a very short time without disorder. Design is controlled by specifying the relationships of tread and riser, the distance apart and size of landings, whether or not curved stairs are allowed, etc., and often, because of the smoke danger, requiring exit stairs to be enclosed in a fireproof tower, with fireproof, self-closing doors at all entrances.

**STALACTITES AND STALAGMITES.** Stalactites are elongated pendent forms of various minerals deposited from solution where very slow drip water may enter a void. Stalagmites are complementary forms of thicker proportions which grow up on the bottom of a cavity from the same drip-water source but whose mineral was deposited after free fall across the open space in the rock. An inclusive name for both forms is dripstone.

The dominant mineral in dripstone deposits is calcium carbonate (see CALCITE) and the largest displays are formed in caves in limestone and dolomite. Other minerals which may be deposited in these forms include other carbonates, opal, chalcedony, limonite and some sulfides. Icicles are stalactites of water. Ice in stalagmitic form is very rare.

Conditions which favour dripstone deposition of calcium carbonates are (1) a source rock above the cavity; (2) downward percolation of water supplied from rain; (3) tight but continuous passageways for this water which determine a very slow drip; (4) adequate air space in the void to allow either (a) evaporation or (b) escape of carbon dioxide from the water which thus loses some of its solvent ability. Minor and imperfect stalactites may hang from the underside of masonry and concrete bridges and arches, and from ceilings of concrete arched tunnels and subways. One-way traffic through such structures may produce forms that hang out of plumb, inclining in the direction taken by recurrent air currents engendered by passing vehicles. Even in some caves, an air circulation is believed to have been the cause of inclined stalactites.

Stalactites, but not stalagmites, commonly exhibit a central tube or the trace of a former tube whose diameter is that of a drop of water hanging by surface tension. Examination will show that the drop on the tip of a growing stalactite leaves a deposit only around its rim. Downward growth of the rim makes the tube.

The simplest stalactite form, therefore, is a thin-walled stone straw, and these fragile forms may reach lengths of two feet or more where air currents have not seriously disturbed the growth. The more common form of a downward-tapering cone is simply a thickening of the primitive straw type by deposition from a film descending the exterior of the pendant. This also makes the concentric structure seen in broken stalactites, slight variations in colour from impurities demarking successive additions. Neither these nor the comparable rings of stalagmite structure are annual rings.

Related to stalagmites are broader, flatter cones on a cave floor which generally grade outward into a sheet of secondary lime known as cave travertine but more specifically as flowstone.

Stalactite forms may grade into very broad pendent leaves, sheets, blades and drapes, whose growth is entirely on the edges. Other variants of the conventional carrot-shaped stalactite may have a bulbous upper portion resembling the form of a radish, beet or turnip. More puzzling than this enlargement is a common ceiling attachment by a slender stem. Compound forms of much complexity may result from continued lateral enlargement of closely adjacent stalactites and stalagmites. Not every stalactite has a complementary stalagmite, and many of the latter may have no stalactite above them. Where the paired relation exists, however, continual elongation of one or both eventually results in a junction and the formation of a column. Large stalagmites and columns have a habit of developing shelves or brackets in vertical series, with depending drapes or relatively small stalactites growing down from the bottom of each.

The slow rate of growth of these calcium carbonate deposits is conditioned by a variety of variable factors. Deposition from drip water indicates saturation of the water under the existing conditions. But these conditions may change so much that deposition will cease although the drip continues. In some cases, solution of a previously growing stalagmite may occur and produce a cratered concavity where once was a projecting conical tip.

Lava caves containing lava stalactites have a wholly different genesis. The cave results from surface solidification of a lava flow during the last stages of its activity. Thus what is essentially a frozen crust may form over still mobile and actively flowing liquid rock. Dwindling of the supply may then leave long tunnels under this crust. Volcanic gases from bubbles in the lava collect under the tunnel roof. Mingled with air from vents in the roof, more intense heating from oxidation may raise the temperature of the gas sufficiently to re-fuse the ceiling rock, which then drips with the remelted lava, which may congeal in place to form rude stalactites.

**STALACTITE WORK**, in architecture, one of the most general characteristics of all of the Islamic styles, consisting of a series of little niches, bracketed out one above the other, or of projecting prismatic forms in rows and tiers, connected at their upper ends by miniature arches. Its infinite varieties may be classified into three groups, the first consisting of those basically niche shaped, in which the concave curve is the most important

BY COURTESY OF U.S. DEPARTMENT OF THE INTERIOR

JUNCTION OF STALACTITES AND STALAGMITES FORMS A COLUMN OF LIMESTONE IN THE GREEN LAKE ROOM, CARLSBAD CAVERNS NATIONAL PARK, CARLSBAD, N.M.

Known as the Veiled Statue, this formation is the result of the deposition of carbonate of lime, carried in solution by descending ground water

feature; the second group includes those in which the vertical edges between the niches are the most important feature, being set at all sorts of angles and having generally prismatic forms; the last group consists of elaborately intersecting, miniature arches. The first two groups occur commonly in Syrian, Moorish and Turkish work and in their simpler forms, in Persia; the last group is typically Persian and is found also in Mogul work in India.

Stalactites are of comparatively late development in Islamic art, the earliest buildings in Syria, Egypt and north Africa showing no traces of them. They seem to appear suddenly all over the Islamic world toward the beginning of the 12th century. Thus simple forms are found in the mosque at Ani in Armenia, built between 1072 and 1110, and they are common in Algiers and Sicily during the course of the century, as in the gate at Chella (1118-84), and in the building, which is known as La Ziza at Palermo (1154).

In Egypt the stalactites appear in panels flanking the main entrance of the El Akmar mosque at Cairo (1125-50). They reached their highest development in the 14th and 15th centuries, becoming the normal decoration for the heads of door niches and the bracketing under cornices and minaret galleries. The richest examples of the prismatic type are to be found in Moorish work in Spain, especially in the intricate wood and plaster ornament of such palaces as the 14th- and 15th-century Alhambra (*q.v.*) in Granada and the 14th-century Alcázar at Seville.

In Turkey, a peculiar type of faceted crystal shape is found and the form became the most common capital decoration.

See ISLAMIC ARCHITECTURE.

**STALIN, JOSEPH VISSARIONOVICH** (DZHUGASHVILI) (1879-1953), leader of the Communist Party of the Soviet Union, prime minister, generalissimo, and dictator of the U.S.S.R., one of the most powerful, complex, and controversial figures in world history. He was born on Dec. 21, 1879, in the Transcaucasian town of Gori, in Georgia.

His father, Vissarion Dzhugashvili, a poor shoemaker, died when Joseph was 11 years old. His mother, Ekaterina, the daughter of a serf, was an illiterate and deeply religious washerwoman. After the death in infancy of three children, Joseph was her only son. She brought him up with much tenderness and devotion and chose for him an ecclesiastical career in the Georgian Orthodox Church.

**The Young Revolutionary.**—Georgian folklore, native tribal traditions, fresh memories of serfdom, and Georgian patriotic (anti-Russian) sentiment were the strongest influences in Joseph's childhood. He attended the parish school at Gori, and in the autumn of 1894 he matriculated at the theological seminary of Tiflis (Tbilisi). He was a very able pupil, a voracious reader, and an ambitious debater. In 1898, while he was still at the seminary, he joined the ranks of Mesame Dasi (the Third Group), a Georgian patriotic and socialist organization; and he came under the influence of Marxism, which was rapidly spreading among the Russian and Georgian intelligentsia. In 1899, when he was about to graduate, he was expelled from the seminary because of his "disloyal" views.

The young Dzhugashvili plunged into revolutionary propaganda and agitation. At the turn of the century the revolutionary movement in Russia shed the ideas of agrarian socialism preached by the Narodniki (*q.v.*) and adopted the Marxist social-democratic program, advocated by G. V. Plekhanov and V. I. Lenin (*qq.v.*) in the journal *Iskra*. Dzhugashvili was a supporter of *Iskra*. In 1901 he was elected to the clandestine Social Democratic Com-

mittee of Tiflis. Police persecution forced him to "go underground." Arrested in April 1902, he remained in prison until the end of 1903. But while in prison he was elected to the Social Democratic Committee guiding the movement in the whole of the Caucasus. Deported to Siberia, he escaped from there and returned to Tiflis early in 1904, shortly after the Social Democratic Party had split into Bolsheviks and Mensheviks. He joined the Bolsheviks, who wielded little influence in Georgia. At this early stage he was already under the overwhelming influence of Lenin's writings; and in local clandestine sheets and periodicals he translated Lenin's ideas from the Russian into the Georgian.

In the revolution of 1905 (see RUSSIAN HISTORY), Dzhugashvili played no conspicuous part, but he was active in the background as an organizer of Bolshevik fighting squads and partisan groups. He had a hand in organizing raids on treasury transports, the so-called exes (expropriations), the raiders "expropriating" government funds and using them to finance the party's revolutionary activity. He first met Lenin at a party conference at Tampere (Tammerfors), in Finland, in 1905. In 1906 and 1907 he participated in party congresses held in Stockholm and London; in opposition to Lenin he advocated a policy of agrarian revolution identical with that later adopted by the Bolsheviks in 1917. After the failure of the 1905 revolution he distinguished himself as the Bolshevik leader of Baku. Many times arrested and deported, he succeeded each time in escaping from the places of exile.

In 1912 the Bolsheviks finally broke with the Mensheviks and formed a separate party. Lenin then "co-opted" Dzhugashvili as member of the new central committee. Stalin (he began to use this pseudonym, the Man of Steel, early in 1913) was the first editor of *Pravda*, which began to appear on May 5, 1912. At the end of that year he attended important Bolshevik conferences in Cracow, in Austrian Poland, and then went to Vienna to write *Marxism and the National Problem*. This important study was a theoretical argument in favour of the Bolshevik program of "self-determination" of oppressed nations. The work established his reputation as a foremost expert in this field, but he was looked upon as a man of action and an organizer, not a theoretician. On his return to St. Petersburg he was again arrested and deported to the Turukhan Province in the polar circle. He remained in exile until the outbreak of the March Revolution of 1917. (See RUSSIAN REVOLUTION.)

**Stalin's Role in 1917.**—Stalin's role in the events of 1917 was not prominent. This was the heyday of the brilliant revolutionary orators and agitators; and Stalin was not one of them. He was overshadowed not only by L. D. Trotsky (*q.v.*), who was much more than an orator and agitator, but by G. E. Zinoviev, A. V. Lunacharski, Aleksandra Kollontai, and other less important Bolshevik leaders. After his return from Siberia in March, he became editor of *Pravda* and adopted a vaguely conciliatory attitude toward the provisional government of Prince G. E. Lvov. Soon afterward the Bolsheviks, prompted by Lenin, embarked upon a revolutionary course of action; but Stalin remained one of their chief organizers and *Pravda's* coeditor. At the height of the anti-Bolshevik campaign in July he organized Lenin's escape from Petrograd; and in the absence of Lenin, Trotsky, L. B. Kamenev, and Zinoviev, he guided the 6th Party Congress immediately after the "July Days." During the famous controversy that developed in September and October between Lenin, advocating an armed rising, and Zinoviev and Kamenev, opposing insurrectionary tactics, Stalin was among Lenin's adherents, although in *Pravda* he attempted to bridge the gulf between the two factions. He was elected member of a Bolshevik insurrectionist "centre" that was to join the Military Revolutionary Committee headed by Trotsky; but he played no part at all in the insurrection itself.

**The People's Commissar.**—After the Bolshevik seizure of power Stalin was appointed commissar of nationalities, and he held this post for nearly five years. Under Lenin's guidance he set out to put into effect the party's program of "self-determination" for oppressed nationalities. One of his first official acts was to proclaim on behalf of the new Russian government the independence of Finland. He participated closely in the drafting of the first Soviet constitutions of 1918 and 1923. In 1919 he was, in addi-

SOVPHOTO  
STALIN

tion, appointed commissar of the Workers' and Peasants' Inspectorate, an important department whose function it was to supervise all other branches of the Soviet administration.

Stalin's voice carried much weight in the inner Bolshevik councils during the civil war, although he continued to be overshadowed by Trotsky, the founder and inspirer of the Red Army. As member of the Council of Defense, political commissar, and inspector of fronts, Stalin was in charge of the defense of Tsaritsyn (later Stalingrad and now Volgograd) in 1918; he organized the defense of Petrograd (Leningrad) against Gen. N. N. Yudenich's offensive in May 1919, and the Battle of Orel in October of the same year, when the Red Army halted Gen. A. I. Denikin's advance on Moscow and passed to the counteroffensive. He served as political commissar with S. M. Budenny's cavalry corps during the advance on Lwow (Lvov) in 1920; and he was in charge of the preparations for the final campaign against Gen. P. N. Wrangel's army and of the dramatic battle of the Perekop Isthmus, the last battle of the civil war. Some of these episodes, especially his role in the defense of Tsaritsyn and in the march to Poland, were the subjects of much controversy. During the civil war an intense rivalry developed between him and Trotsky, the commissar of war. Not without justification, Trotsky charged Stalin with surreptitiously supporting the left-wing Communists who were opposed to the employment of old army officers in the Red Army and to the army's centralized structure and discipline established by Trotsky. Trotsky's influence remained paramount, but even in 1919 Stalin wielded enough power to bring about the dismissal of I. I. Vatsetis, Trotsky's protégé, from the post of commander in chief and his replacement by Gen. Sergei S. Kamenev. After the civil war, in February 1921, Stalin initiated the Bolshevik invasion of Georgia without the knowledge of Trotsky or the commander in chief.

In April 1922, after the 11th Party Congress, the last congress attended by Lenin, Stalin was appointed secretary-general of the party and relinquished his posts in the Council of People's Commissars. This was a turning point in his career: as secretary-general he soon came to control the whole machinery of the party and through it the government.

**The Succession to Lenin.**—Lenin's illness in 1923 and his death (January 1924) coincided with a crisis of the revolutionary regime. The Bolsheviks had from the beginning denied political freedom to the old ruling classes and their parties who opposed arms in hand the "proletarian dictatorship." But the Bolsheviks had also pledged to respect and secure "Soviet democracy," that is, freedom of political expression for the working classes and their parties. The proletarian dictatorship had been conceived as a system of representative government, but instead of a parliament, the councils of workers' and peasants' deputies were to form the representative organs. Toward the end of the Lenin era, however, the regime had already developed into a single-party system. All non-Bolshevik parties had been banned, and only within Bolshevik ranks was some freedom of expression preserved. Inevitably the question arose whether the Bolsheviks themselves could enjoy the freedom they denied to others. The other critical development concerned the party's international orientation. The hope for an imminent spread of revolution abroad, which had inspired the Bolsheviks, was decisively undermined in 1923 after the defeat of Communism in Germany. Bolshevik Russia was at last recognized by most bourgeois governments, but as a Communist state it stood alone. Bolshevism was withdrawing into its national shell and was ill at ease with the revolutionary internationalism of the Lenin era. All these issues were brought to a head in the struggle over the succession to Lenin.

In 1923 Stalin, Zinoviev, and L. B. Kamenev formed a triumvirate with the purpose of debarring from power Trotsky, who was generally regarded as Lenin's successor. In his last will Lenin advised his followers to remove Stalin from the general secretariat of the party on the ground that Stalin was rude and inclined to abuse power. But Stalin, supported by Zinoviev and Kamenev, retained his office. In a constant struggle against his opponents he abolished whatever freedom of expression still existed within the party and transformed the party into a "monolithic" body. In

the autumn of 1924 he expounded the theory of "socialism in one country," proclaiming the self-sufficiency of the Russian Revolution. This doctrinal innovation marked a departure from Leninist internationalism, although Stalin did his utmost to present his views as orthodox Leninism.

In April 1925, having defeated Trotsky, Stalin openly broke with the other members of the triumvirate and, at the 14th Party Congress, joined hands with the party's right wing led by N. I. Bukharin, A. I. Rykov, and M. P. Tomski. Zinoviev and Kamenev, on the other hand, made common cause with Trotsky. They denounced the theory of "socialism in one country," advocated a policy of industrialization and a struggle against the kulaks (well-to-do farmers), and demanded the restoration of "inner party democracy." At this stage Stalin, anxious to keep in line with Bukharin's moderate group, pursued a very cautious policy; he refused to undertake a drive against the kulaks and treated the demand for rapid industrialization as unreal. But in 1928–29, after he had defeated and expelled from the party Trotsky, Zinoviev, Kamenev, and their followers, Stalin turned against Bukharin, Rykov, and Tomski. He then effected a most drastic change of policy and began to industrialize the U.S.S.R. and to collectivize agriculture with a speed and ruthlessness that horrified the original advocates of these policies. In 1929 he expelled Trotsky from the U.S.S.R. and forced all opposition leaders, right and left, to surrender and "recant." He had become undisputed master of the U.S.S.R.

**Industrialization and Collectivization.**—"We are 50 or 100 years behind the advanced countries. We must make good this lag in 10 years. Either we do it or they crush us." Thus Stalin explained the purpose of industrialization to a conference of industrial managers on Feb. 4, 1931. In the course of the decade the U.S.S.R. was indeed transformed from one of the most backward states into a great industrial power; this was one of the factors that was to assure Soviet victory in World War II. Stalin emphatically insisted on the need to develop primarily the heavy industries. Industrialization was consequently accompanied by an extreme scarcity of consumer goods and by widespread popular discontent. Stalin violently suppressed the discontent. With utmost determination he enforced a policy of incentive rewards to skilled workers, technicians, and administrators, which provoked much indignation among party members brought up in an egalitarian spirit. They denounced Stalin as the leader of new privileged social groups.

Industrialization on the gigantic scale envisaged in the successive five-year plans encountered many other difficulties that might have baffled and defeated a government less ruthless than Stalin's. In the 1930s alone about 25,000,000 peasants were forcibly shifted from rural areas to the industrial centres and transformed into factory workers by means of intensive training and with the help of an extremely harsh industrial discipline. Throughout the Stalin era the U.S.S.R.'s urban population grew by about 45,000,000. In order to free labour for industry and to secure food for the swelling urban population, Stalin collectivized farming. In 1929 there were about 25,000,000 primitive rural smallholdings in the U.S.S.R. In 1952 there were 100,000 large and highly mechanized collective farms. The peasantry at first bitterly resisted collectivization. Stalin broke its resistance and ordered the deportation of many kulaks into the notorious labour camps. Despite initial failures and famines, the new system of farming achieved a degree of consolidation in later years that enabled it to survive the shocks of World War II and its aftermath; but it did not attain high productivity.

**The Great Purges.**—At the height of the industrial drive, shortly after he had introduced the quasi-liberal constitution of 1936, Stalin staged the great purge trials in which most of the old Bolsheviks and some military leaders were charged with treason, terrorism, and espionage and brought to "confess" guilt. In this way Stalin exterminated the men who might have been able to overthrow him and form an alternative government during a national crisis. The purges, carried out on a mass scale, imparted to the Stalinist regime its peculiar terroristic character.

**Foreign Policy Prior to 1941.**—The national crisis that Stalin

feared was approaching with World War II. After Hitler's rise to power in Germany, Stalin grappled with a dilemma: should he enter an anti-Hitler coalition with the Western Powers or an agreement with Hitler? At first his diplomacy aimed at building up the anti-Hitler coalition, but finding the West reluctant to commit itself to an alliance with the U.S.S.R., Stalin hinted at his readiness to come to terms with Hitler in a speech at the 18th Party Congress in March 1939. In August, with the agreement signed in Moscow by his foreign minister, V. M. Molotov, and the German foreign minister, J. von Ribbentrop, he struck the bargain with Hitler under which the U.S.S.R. and Germany divided their spheres of influence in Eastern Europe, and the U.S.S.R. avoided immediate involvement in the war that broke out a few days later. (See WORLD WAR II.)

The twists and turns of Stalin's foreign policy affected closely the attitude of the Communist International. After a long series of purges and expulsions Stalin succeeded in transforming the International into a "monolithic" organization, identifying the interests of world Communism with Stalin's dogmas and policies. Thus the Communist International had supported Chiang Kai-shek during the Chinese revolution of 1925-27 when Soviet diplomacy regarded the Chinese generalissimo as its ally. In 1935-39 the Communist parties organized the "popular fronts" to help the U.S.S.R. in its search for bourgeois democratic allies against Hitler. In 1939 they lent moral support to the Ribbentrop-Molotov pact.

**Generalissimo.**—The German attack on the U.S.S.R., started on June 22, 1941, caught Stalin unawares, as he himself later publicly admitted. In preparation for critical times he had assumed the premiership on May 6, but he still hoped to be able to postpone the inevitable conflict between the U.S.S.R. and Germany. After the German attack he formed the State Defense Committee, consisting of himself, V. M. Molotov, G. M. Malenkov, L. P. Beria, and K. E. Voroshilov. On July 3, 1941, he made the famous call on the Soviet people to "scorch the earth" occupied by the invader. "In occupied regions conditions must be made unbearable for the enemy and all his accomplices. They must be hounded and annihilated at every step, and all their measures frustrated."

Throughout World War II Stalin was personally responsible for the major military and diplomatic decisions of his government, although he left considerable freedom of initiative to his generals. After the initial period of confusion, his strategy, following the traditional Russian pattern of 1812, was to withdraw, to conserve strength, to gather new reserves, and to force the attacker to spend his impetus and extend his lines—only after that could the U.S.S.R. pass to the offensive. He displayed extraordinary will power, tenacity, and coolheadedness. He stayed on in the Kremlin when Hitler's armies stood at the gates of Moscow and the Soviet government was evacuated to Kuibyshev. From the Kremlin he organized a hasty yet effective evacuation from the threatened areas of industrial plants and of many millions of industrial workers. The shifting of industry from west to east enabled the U.S.S.R. to recover from the first blows and to build up a new and enormous armed power.

Stalin's political conduct of the war was characterized by strong emphasis on Russian patriotism, nationalism, and traditionalism. Evoking the memories of 1812, he described the struggle as the Great Patriotic War, and he extolled the national heroes of Mother Russia and the military traditions of Peter the Great, Suvorov, and Kutuzov. He rehabilitated the Orthodox Church and disbanded the Communist International. These moves, dictated primarily by considerations of domestic policy, were calculated to meet the needs of his foreign policy as well. He was anxious to preserve the alliance with the Western Powers, and his conduct of the war in a nationalist rather than in a revolutionary spirit helped keep the grand alliance together, despite inner contradictions and tensions.

Some of the tensions were due to the fact that the Western Allies repeatedly postponed the opening of the "second front" in Western Europe. This was the main point in Stalin's controversies with Winston Churchill in 1942-43. But as the Soviet Army broke Germany's military power in the "ten offensives" that

followed the Battle of Stalingrad in 1943, this issue lost importance. The course of the war revealed a profound shift in the international balance of power, a shift due primarily to the growth of Soviet and U.S. power. Stalin bargained adroitly during the conferences at Teheran and Yalta, and his diplomacy secured for the U.S.S.R. the predominance in Eastern and Central Europe that was in any case bound to result from the success of Soviet arms. The Teheran and Yalta agreements contained, however, the seeds of the discord that was to lead to the breakdown of the grand alliance after the war. Stalin was also the presiding spirit at the Potsdam Conference of July-August 1945, at which he committed the U.S.S.R. to join the United States and Great Britain in the war against Japan, and at which he worked out together with the Western Allies a rather impracticable armistice regime for occupied Germany.

**Stalin's Last Years.**—The year 1945 marked the climax in Stalin's crowded and checkered career. As generalissimo and uncontested leader he was surrounded by an adulation and a cult that assumed its most grotesque forms toward the end of his life. Soviet scientists, writers, musicians, linguists, philosophers, and others were made to accept his judgment as final. Underlying the bizarre cult were Stalin's indubitable achievements. He was the originator of planned economy; he found Russia working with wooden plows and left it equipped with atomic reactors; and he was "father of victory." But his achievement was marred by the despotism and cruelty of his dictatorship; and the patriarchal character of his rule, suited perhaps to the mentality of an illiterate and backward people, became an anachronism in the industrialized and modernized Russia of the 1950s.

Stalin's personal role in the conduct of Soviet foreign policy from 1945 to 1953 remained enigmatic. Communists and anti-Communists alike had seen in him the architect of the revolutions in Eastern Europe and China. In the light of the documentary information available, this view appears to be ill founded. From the beginning Stalin was opposed to Tito's revolutionary policies in Yugoslavia; and he viewed without sympathy Mao Tse-tung's revolutionary strategy and tactics in China. On the other hand, he undoubtedly inspired some of the Communist revolutions in Eastern Europe; and he expected all Communist revolutions, those he had supported and those he had obstructed, to adopt the Stalin cult. During his last years a struggle developed in his entourage between the diehards of Stalinism and those who stood for domestic reform, and also between adherents of a "tough" foreign policy and advocates of conciliation. Stalin tried to keep a balance between the conflicting attitudes and to shape Soviet policy as the resultant of the conflicting trends. After his death his successors became openly divided over these issues, and also in their attitudes toward the Stalinist legacy.

Stalin died from cerebral hemorrhage in the Kremlin on March 5, 1953.

Stalin's writings include *Marxism and the National and Colonial Question* (written and first published in 1912-13; definitive ed. 1934), *Problems of Leninism* (1st collection of articles 1926; 11th ed. 1939), co-author of *History of the Communist Party of the Soviet Union* (1938; new ed. 1952), *Concerning Marxism in Linguistics* (1951), and *Economic Problems of Socialism in the U.S.S.R.* (1952). A collected edition of Stalin's works appeared in 1946-50.

**STALL**, in church architecture, is a fixed seat enclosed at the back and separated from adjacent stalls at the sides by high projecting arms. Stalls are placed in one or more rows on the north and south sides of the chancel in cathedrals, monastic churches, and large parish churches. In an English cathedral the canons

and prebendaries each have a stall assigned to them. In the chapels of the various knightly orders the stalls are assigned to the members of the order, thus, in St. George's Chapel, Windsor, are the stalls of the knights of the Garter, in Henry VII's Chapel in Westminster Abbey are those of the knights of the Bath, adorned with the stall plates emblazoned with the arms of the knight occupying the stall, above which is suspended his banner. Architecturally considered, the stalls of a cathedral or church are a marked feature of the interior adornment. They are richly carved, and are frequently surmounted by canopies of tabernacle work. The seats generally can be folded back so as to allow the occupant to stand upright or kneel; beneath the seat, especially in monastic churches, is fixed a small bracket, a *miserere*, which affords a slight rest for the person while standing. Among specimens of carved stalls may be mentioned the Early Decorated stalls in Winchester Cathedral (1296); the Early Perpendicular ones in Lincoln Minster (c. 1370); the early 15th-century canopies in Norwich Cathedral (15th century); and the towering corner stalls with their ornate carving filled with figures in Amiens Cathedral (1508-20).

**STALYBRIDGE**, a municipal borough of Cheshire, Eng., lies 8 mi. (13 km.) E of Manchester. Pop. (1961) 21,947. It was incorporated in 1857, and its boundaries were extended in 1881 and 1936. Stalybridge is one of the oldest cotton towns (first cotton mill 1776), but its industries now include—besides cotton—engineering, cable making, and plastics. The town has two extensive parks (one jointly with Ashton-under-Lyne), and there is a pleasant residential district on the Derbyshire side. There is a municipal art gallery. Stayley Hall, the home of the family from which the town derives its name, was erected about 1343.

**STAMBOLISKI, ALEKSANDR** (1879-1923), Bulgarian statesman, the fearless opponent of King Ferdinand's pro-German policy in World War I and the formidable champion of the peasantry as head of the government from 1920 to 1923, was born at Slavovitsa on March 1, 1879. He attended the agricultural college of Halle in Germany. On returning to Bulgaria, aged 18, he took up journalism and, in 1902, became editor of the organ of the newly formed Agrarian League. Six years later he was elected to the *Narodno Sobranie* (National Assembly), where he led the Agrarian Party. He began to organize the peasant masses, who formed 80% of the population of Bulgaria, into agricultural associations. In 1911, when the *Narodno Sobranie* met at Turnovo to amend the constitution, his first conflict with King Ferdinand (*q.v.*) occurred. After the Treaty of Bucharest (1913; see *BALKAN WARS*), Stamboliski and the Agrarians were unmerciful in their criticisms of Ferdinand's policy, though deterred from extreme measures by fear of external complications. His opposition to Ferdinand came to a head in 1915 during the negotiations that preceded Bulgaria's entry into World War I. In spite of the king's anger, pressure from the government, and the growing influence of the Central Powers, Stamboliski strongly resisted the government's warlike policy. Summoned before the king, he threatened him with violence if he should fight against the Allies, reminding him that he had a crown to lose. Ferdinand ordered his arrest. Stamboliski was tried by court-martial and condemned to penal servitude for life.

In September 1918, when the resistance of the Bulgarian troops began to crumble, Ferdinand released Stamboliski, who left for the Macedonian front. He returned at the head of the insurrectionary troops, and their arrival at Sofia resulted in Ferdinand's abdication and flight. A supporter of the new ruler, King Boris, Stamboliski became a member of the Cabinet in January 1919 and prime minister in October. He then went to Paris to sign the Treaty of Neuilly. Having dissolved the *Sobranie* in February 1920, he was returned to power in the elections of March at the head of a homogeneous Agrarian majority.

The Agrarians under Stamboliski ruled Bulgaria with a rod of iron. They had Vasil Radoslavov's Cabinet, which had brought Bulgaria into World War I, condemned to death by popular vote. Stamboliski's determination to promote the interests of the peasantry against the bourgeoisie of the capital was expressed in the words: "Sofia, that Sodom, that Gomorrah, may disappear . . . I

shall not weep for it." Through his influence Bulgaria loyally carried out the terms of the Treaty of Neuilly, won the esteem of the Allies, and secured a reduction of reparations. Stamboliski also made persistent efforts to improve Bulgaria's relations with Yugoslavia, with which country he concluded an agreement at Nis (1922). His ultimate ideal was probably some kind of federal South Slav state, embracing Bulgaria.

The overthrow of the government by a military conspiracy on June 9, 1923, was caused partly by dissatisfaction with Stamboliski's domestic policy and partly by the influence of the Macedonian Party. The change of regime took place in one night, the Agrarian ministers being arrested in their homes. Stamboliski, pursued by an armed detachment to his native village, fled across the mountains, hoping to reach the frontier, but was overtaken and shot on June 14. Stamboliski's demeanour was fierce and his movements ungainly; his rough-hewn face was crowned by a mass of black hair; he impressed everyone with his strength and the sincerity of his advocacy of a "Green International" to unite the peasants of all countries.

See N. D. Petkov, *Aleksandr Stamboliski* (1946). (N. I. M.)

**STAMBULOV, STEFAN** (1854-1895), Bulgarian statesman, a participant in the emancipation of his country from Turkish rule, an effective opponent of Russian influence, and for seven years the despotic head of a government with practically unlimited power. He was born on Jan. 31, 1854, an innkeeper's son, at Turnovo, the ancient capital of the Bulgars. He went to Russia to study for the priesthood at the Odessa seminary but was expelled for associating with Nihilists. Going to Rumania, he linked himself with Bulgarian revolutionary committees at Bucharest and at Giurgiu. Returning to Bulgaria, he led an anti-Turkish rising at Nova Zagora in 1875 and organized another at Orekhovitsa in 1876. Having fought as a volunteer in the Serbian campaign against Turkey (autumn 1876), he joined the Bulgarian irregular contingent with the Russian forces in the war of 1877-78 (see *RUSO-TURKISH WARS*). After the Congress of Berlin (*q.v.*) he settled at Turnovo as a lawyer. Soon elected to the *Sobranie* (National Assembly), he became president of it in 1884. He was instrumental in persuading Prince Alexander (*q.v.*) to accept the union of Eastern Rumelia with Bulgaria in 1885. When the Serbo-Bulgarian War (*q.v.*) broke out in consequence, Stambulov served as a soldier in the army. (See also *BULGARIA: History*.)

When pro-Russian officers abducted Prince Alexander (August 1886), Stambulov set up a government loyal to him at Turnovo, issued a manifesto to the nation, nominated his brother-in-law, Gen. Sava Mutkurov, commander in chief of the army, and invited the prince to return. His measures led to the downfall of the provisional government set up by the pro-Russian faction at Sofia. On Prince Alexander's final abdication (Sept. 8) Stambulov became head of a council of regency, with Mutkurov and Petko Karavelov as his colleagues; the latter, however, soon made way for Stambulov's friend Georgi Zhivkov. Stambulov frustrated the mission of Gen. N. V. Kaulbars, the Russian emperor Alexander III's special commissioner to Bulgaria; held elections for the *Sobranie*, despite the interdiction of Russia; and eventually secured the election of Prince Ferdinand (*q.v.*) of Saxe-Coburg-Gotha to the vacant throne (July 7, 1887). Under Ferdinand he became prime minister and minister of the interior.

The aim of Stambulov's foreign policy was to obtain the recognition of Prince Ferdinand and to win the support of the Triple Alliance (Austria-Hungary, Germany, and Italy) and of Great Britain against Russian interference in Bulgaria. He gained the confidence of the Turkish government and secured recognition from it for a few Bulgarian bishops in Macedonia (see *MACEDONIAN QUESTION*). With the assistance of Austria-Hungary and Great Britain he negotiated large foreign loans, which enabled him to develop the military strength of Bulgaria.

Stambulov ruthlessly stamped out recurrent plots and armed risings engineered by equally ruthless political opponents who were backed by Pan-Slavist circles in Russia. Allowing no clear distinction between party strife and sedition, he used his police, and sometimes the army, to deal with either. Maj. Konstantin Panitsa, after leading a conspiracy, was shot at Sofia in 1890; four

political opponents were hanged in 1891; and Karavelov was sentenced to five years' imprisonment. Among the deadliest enemies of Stambulov's regime were the Macedonian committees, responsible for the assassination of his finance minister, Khristo Belchev, in 1891, and of his minister in Istanbul, Georgi Vlkovich, in 1892.

Stambulov's arrogance, and the growing violence of the opposition throughout the country, became unbearable to Prince Ferdinand, who wanted, moreover, an accommodation with Russia. He contrived to get his unmanageable prime minister to resign and accepted his resignation in May 1894. Stambulov was now exposed to the vengeance of his enemies. Attacked and barbarously mutilated by a band of Macedonian assassins in the streets of Sofia on July 15, 1895, he died of his injuries three days later.

(J. D. B.; N. I. M.)

**STAMFORD**, a municipal borough in the Parts of Kesteven, Lincolnshire, Eng., on the River Welland, the boundary between Lincolnshire and Northamptonshire. Pop. (1961) 11,743. It lies 11 mi. NW of Peterborough in the Rutland and Stamford parliamentary division. Stamford is a very ancient market town, built of local gray stone and once famous for its cloth. Its position on the Great North Road and on the borders of the Fens contributed to its importance. Its modern industries include general and agricultural engineering, brick and tilemaking, and the manufacture of plastics and toys. Of the old churches six remain: St. Mary's (with a Decorated spire), All Saints (with fine brasses), and St. Martin's (which contains the Burghley tombs) are the most noteworthy. There are remains of the 7th-century Benedictine priory of St. Leonard and a west gate of the Carmelite monastery (1291). Browne's Hospital is one of the almshouses known as Calises, from the wool merchants of Calais. There was a Danish fort at Stamford, which later became one of the five Danish boroughs. A charter of Edgar dated A.D. 972 mentions a market and a mint. In the reign of Edward the Confessor Stamford was a royal borough governed by 12 lawmen. The Norman castle was built before 1086. Henry III gave the town a charter in 1256 and it was incorporated in 1461–62.

Stamford was known for its wool trade, its churches, and its monastic schools, and in 1333 was chosen as the headquarters of the students who seceded from Oxford. An Early Decorated doorway (1300) remains of Brasenose Hall. The attempt to establish a regular university was prohibited by royal authority. The history of the place centred around the family of Cecil when the great Lord Burghley built Burghley House (1577–85), a fine quadrangular mansion south of the town, now the seat of the marquess of Exeter. The house contains notable art collections.

**STAMFORD**, a city of Connecticut, U.S., is 35 mi. NE of New York City, on Long Island Sound. Founded in 1641 by 29 secessionists from the Wethersfield Church, the town was under the New Haven Colony, which later merged with the Hartford Colony into what became the state of Connecticut. In 1644, one-third of the population of Stamford emigrated to Long Island, but the town continued to grow as an agricultural, lumber, leather, and shipbuilding community. By the time of the American Revolution it had approximately 5,000 residents. A city government was formed within the town in 1893, and the town and city merged in 1949. The population quadrupled in the first half of the 20th century, reaching 74,293 in the 1950 census. The population in 1960 was 92,713 for the city and 178,409 for the standard metropolitan statistical area, comprising Stamford city and Darien, Greenwich, and New Canaan towns of Fairfield County. (For comparative population figures, see table in CONNECTICUT: *Population*.)

The countryside still retains much of a rural New England atmosphere north of the Merritt Parkway, which bisects the city, but rapid population growth marks its emergence as a suburban industrial, commercial, and commuter centre. It is the site of major chemical research laboratories; manufactures include chemical products, postage meters, ball bearings, and die castings. In addition to arterial highway and major rail facilities, the city is connected to New York by regular helicopter service and is near the Westchester County, N.Y., airport. It is served by public

and private secondary schools, a branch campus of the University of Connecticut, and a museum and nature centre. Recreational facilities include municipal beaches, a municipal golf course, private and public marinas, about 600 ac. of parkland, and numerous private clubs.

(W. L. T.)

**STAMITZ**, Czech family of musicians settled at Mannheim, in the Palatinate, where they exercised a great influence on the development of the symphony.

JOHANN WENZEL ANTON STAMITZ (1717–1757) was born at Deutschbrod (now Havlickuv Brod, Czech.) on June 19, 1717. Little is known of his early life, except that he received his first musical tuition from his father before going to a Jesuit school. He appeared as a violinist at the coronation of the emperor Charles VII in Frankfurt am Main in 1742, but it appears likely that he was already in the musical establishment of the elector palatine at Mannheim, where he was later made director of the court chamber music.

Stamitz brought the Mannheim court orchestra to a standard unrivaled both for precision and scope of expression. Although he did not invent the crescendo and diminuendo effects in orchestral playing, he developed them as a feature of his style, which was then imitated by other Mannheim and later by other European musicians. Another characteristic of his style was the use of "sighing" suspensions, especially at cadences. These became incorporated in *galante* music throughout Europe. His use of the minuet-and-trio as the third movement of a four-movement symphony was similarly adopted by classical composers. His orchestral trios, a *galante* version of the Baroque sonata, were perhaps more influential in the development of the sonata form than were his symphonies, since they were more regular in design.

It is indeed difficult to overestimate Stamitz' influence in these various fields. Although contemporary composers in Berlin, Vienna, and in Italy likewise developed some of these features, it was the first generation of Mannheimers (Stamitz and his associates, F. X. Richter, A. Filtz, I. Holzbauer, and F. Beck) who were most influential in establishing the mid-18th-century style of orchestral writing.

Stamitz' most advanced symphony was composed when Mozart was still an infant. He died at Mannheim on March 27, 1757.

CARL PHILIPP STAMITZ (1745–1801), son of the above, was a leading composer of the second Mannheim generation. Born on May 7, 1745, he wrote a large number of instrumental works, including symphonies, more extended than those of his father: concertos and concertante works for various instruments, quartets, trios, and sonatas. These were published in Paris and London. He left Mannheim with his younger brother JOHANN ANTON STAMITZ (1754–c. 1809), settled in Paris, and visited England and Russia. Carl Stamitz died at Jena on Nov. 9, 1801.

The works of the Stamitz family, together with thematic catalogues and biographical introductions, appear in *Denkmäler deutscher Tonkunst in Bayern*, ed. by H. Riemann, vol. iii, vii, xv, and xvi.

(Cs. Ch.)

**STAMMERING:** see SPEECH DISORDERS.

**STAMMLER, RUDOLF** (1856–1938), German jurist and the most influential legal philosopher of the early 20th century, especially in Germany, Spain, and Latin America, was born on Feb. 19, 1856, in Alsfeld (Hesse). He was professor of law in Marburg (1882–84), Giessen (1884), Halle (1885–1916), and Berlin (1916–23).

Stammler broke the dominance of legal positivism and historicism and directed legal philosophy toward neo-Kantian ideas by developing a modernized philosophy of natural law. By distinguishing the "concept" of law, which is a purely formal definition, from the "idea" of law, which is the realization of justice, he reintroduced into jurisprudence the search for ideals to which law ought to conform. These ideals, however, unlike the immutable law of nature of the classical period, constituted a "natural law with a changing content"; i.e., they served as a broad criterion

to judge the degree of social harmony attainable in a particular place and time. Stammeler's work, at once philosophical and sociological, directed attention to the ideal and the concrete, the universally valid and the varying, contents of justice.

One of his important works, *Die Lehre von richtigen Recht* (new ed., 1926), was translated by I. Husik as *The Theory of Justice* (1925). Stammeler died April 25, 1938, at Wernigerode.

See Morris Ginsberg, "Stammeler's Philosophy of Law," in *Modern Theories of Law* (1933), and George H. Sabine, "Rudolph Stammeler's Critical Philosophy of Law," 18 *Cornell Law Quarterly* 321 (1933). (N. S. Tr.; X.)

**STANDARD, BATTLE OF THE**, fought on Cowton Moor near Northallerton (Yorkshire) on Aug. 22, 1138, between the Scots under King David I and the English, inspired by Archbishop Thurstan of York and led by William of Aumale, later earl of York, resulted in the total defeat of the Scottish Army. King David had invaded England in support of his niece, the empress Matilda, and of his own claims to Northumberland and Cumberland. He had a vast host, but he was short of armoured troops. The English were encouraged by the timely arrival of cavalry sent by King Stephen; otherwise, their army was recruited chiefly from Yorkshire, Norman knights mingling with English peasantry, and all fighting on foot. The battle took its name from the English "standard," a mast mounted on a cart and bearing the Host and the banners of the Yorkshire saints, Peter of York, Wilfrid of Ripon, and John of Beverley. The victory was due to courage and a skilful combination of archers with mailclad knights. Complete though it was, King Stephen was too weak to exploit it, and King David retained control of the northern counties throughout his reign. (G. W. S. B.)

**STANDARD DEVIATION**, in statistics, is a measure of the variability (dispersion or spread) of any set of numerical values around their arithmetic mean (see MEAN). Suppose  $X_1, X_2, \dots, X_n$  are the  $n$  values in a set; for example,  $n (= 5)$  students earn test scores  $X$  of 80, 81, 82, 83, 84, respectively. Their arithmetic mean  $M$  is the sum of these scores  $\Sigma X$  divided by  $n$ ; i.e.,  $M = \Sigma X/n = 410/5 = 82$ . Each score falls at a specific distance from  $M$ ; this distance is called the deviation  $x$  for that score, and  $x = X - M$ . For  $X = 80$ , the deviation  $x = 80 - 82 = -2$ , showing that the score of 80 is 2 units below the arithmetic mean of the set. In this way the five deviations for the students are  $-2, -1, 0, 1, 2$ , respectively.

The standard deviation  $\sigma$  is defined as the square root of the arithmetic mean of the squared deviations:

$$\sigma = \sqrt{\frac{\Sigma x^2}{n}}$$

and  $\sigma^2$  is called the variance of the set. In this case  $\Sigma x^2 = (-2)^2 + (-1)^2 + (0)^2 + (1)^2 + (2)^2 = 10$ , and  $\sigma = \sqrt{10/5} = \sqrt{2}$ .

If any set of values forms a normal (Gaussian) distribution (see ERRORS, THEORY OF), about 99.7% of all the values fall within the range  $M \pm 3\sigma$ , about 95% within  $M \pm 2\sigma$ , and about 68% within  $M \pm \sigma$ . The standard deviation is more commonly used than are other less reliable measures of variability, which include: the total range (the range between the high and low values); the semi-interquartile range (half the range covered by the middle 50% of the values); and the average deviation (or mean deviation, defined as the arithmetic mean of the absolute values of the deviations  $x$ ). All are interpreted in the same general way: the larger the measure of variability, the wider the spread of values within the set.

The standard deviation, aside from being used to describe empirically collected sets of data, is also used to indicate the dispersion of probability distributions. More precisely, suppose a discrete random variable with values  $X$  has probabilities  $p(X_1), p(X_2), \dots, p(X_n)$ . Let  $\mu = X_1p(X_1) + X_2p(X_2) + \dots + X_np(X_n)$ . The variance of the random variable is defined as

$$\sigma^2 = (X_1 - \mu)^2p(X_1) + (X_2 - \mu)^2p(X_2) + \dots + (X_n - \mu)^2p(X_n)$$

The standard deviation of the variable is simply the square root of the quantity on the right.

In the case of a continuous random variable  $X$  having probability density function  $f(X)$  on the interval  $(a, b)$  similarly

$$\mu = \int_a^b Xf(X)dX \text{ and } \sigma^2 = \int_a^b (X - \mu)^2f(X)dX$$

**STANDARDIZATION**, the process of developing and bringing about the utilization of standards. While standardization of some kind or degree is part of almost every human activity, normal usage of the term refers to planned and systematic industrial standardization. In the broadest sense a standard is anything used to measure; e.g., a standard of conduct, a standard of value or a standard of weight or length. This discussion, however, deals mainly with the nature and importance of standardization in industry rather than the evolution of standards in social customs, language, games, music or law.

**Classifications of Standards.**—Since industrial standards may cover anything from product attributes to safety practices it is well to start by giving a definition for the word "standard" that is applicable in every context: A standard is that which has been selected as a model to which objects or actions may be compared. In every case a standard provides a criterion for judgment and its form thus depends on what is to be judged and how it is to be judged. Standards may be devices or instruments such as precision-gauge blocks, light meters or trip scales for making comparisons of size, weight, colour or other attributes. They may be physical models to which things are compared to determine whether, within agreed limits, they are identical. The term is also applied to written mathematical or symbolical descriptions, drawings or formulas setting forth the important features of objects to be produced or actions to be performed.

Company standards are those developed or adopted by a single enterprise for its own use. Industrial standards are those accepted and followed by a group of firms with similar activities and products. National standards are those promulgated by interindustrial or governmental standardizing bodies. International standards are issued by organizations such as the Universal Postal union, the International Wool Textile organization and the International Organization for Standardization. A business firm in its operations may find it useful to make reference to standards drawn from any or all of these sources.

From the standpoint of the individual company where industrial standards find their principal use, standards may be classified as: (1) technical if they deal with products, materials, methods and equipment; (2) managerial if they deal with administrative practices and procedures; (3) substantive if they deal with what is to be done; and (4) procedural if they describe how something is to be accomplished. Some standards are applicable throughout the company while others apply to only one department. From the point of view of their intended use, standards may be classified as follows:

a. Engineering standards applied in technical work and including properties of materials, fits and tolerances, terminology, drafting practices and the like.

b. Product standards intended to describe attributes and ingredients of manufactured items and embodied in drawings, formulas, material lists, descriptions or models.

c. Production standards for processes, methods, operations and equipment included in technical specifications, inspection and test methods, machine setup drawings and operation sheets.

d. Purchasing standards covering specifications for materials, parts, equipment and supplies bought by the firm.

e. Office and procedural standards referring to record-keeping, procedures for production and inventory control, report forms, methods of analysis, budgeting and cost accounting and other administrative practices.

f. Safety standards on machine operations, plant housekeeping, identification of hazards and personnel department.

**Importance of Standardization.**—Standards and the benefits derived from them are so much taken for granted that their importance is not appreciated until an annoyance or emergency stemming from incomplete standardization or utter lack of it is

encountered. The traveler abroad finds an electrical appliance designed to operate on one cycle basis of electricity does not operate on another. The purchaser of an imported article discovers that metric sizes do not mesh with feet and inches. The homeowner learns that the replacement part manufactured for the current model of the dishwasher he owns does not fit his earlier model without costly adaptation. The housewife's food bargain does not turn out to be such a bargain when she sees that Grade A does not mean the same thing for butter that it does for canned fruit.

Modern mass production and mass marketing could not exist in anything like their present forms without comprehensive standardization. Without standards there could be no manufacture on the basis of interchangeable parts. Without standards, manufacturers could not accurately communicate about materials with scattered suppliers and would have to spend more time inspecting incoming items. Without product standards, buyers could not rely on brand names as indicators of consistent quality. The first cost of complicated production equipment would be much higher than it is now and would be much more expensive to maintain if standard equipment components were not available. Standards play a vital role at every point in the complex system of communication, transportation, production and exchange which must operate smoothly to produce and distribute large quantities of low-cost goods in an advanced economy.

**Standards as Management Tools.**—Standardization enables industry to retain and build on its experience to produce better products, for standards are one of the principal forms in which technical knowledge is recorded. By liberating effort that would otherwise have to be expended in rediscovering and reinventing, standards aid in increasing the productivity of industry on which material progress ultimately depends. The use of standards embodying the most economical available methods reduces costs and conserves resources. But while industrial standardization is responsive to consumer needs and desires, its utility for managerial purposes gives it its strongest impetus.

It is management's job to plan, organize and control company operations. Expression of plans via standards and application of systems of control in which deviations from standards cause corrective measures to be taken permit managers to delegate routine tasks and concentrate on major decisions. Extensive use of standards makes for clarity in communication and facilitates coordination. It is generally accepted that standards help management find the best solutions to problems whether they concern product qualities, material properties, process characteristics or operating methods. As standards reach beyond individual companies to suppliers and users of products, further advantages appear.

Standards for products that prevent needless variation and avoid the waste of excessive quality lead in turn to production economies: cheaper materials may be made to serve, painstaking production steps eliminated, inspection requirements reduced and simpler equipment and operations employed. Reduction of product variety also brings dividends through design simplification, making the use of special equipment feasible by permitting longer production runs on fewer items, reduction of inventories and use of simpler planning and control procedures.

**Company Standards Programs.**—Every company has standards but not every company consciously pursues standardization as a means of cost reduction and improvement of operations. Many companies handle standards problems informally; they do not systematically review and codify their standards or use them as an integral part of the management process. Companies that do have formal programs for the development and administration of standards employ a variety of organizational arrangements and procedures but they usually have some things in common. Some have a separate group headed by a standards engineer devoting full time to standards work; in other companies the work may be assigned to permanent committees or to committees convened for particular standards projects. In many firms consultative or coordinative committees are established in addition to the staff groups or working committees which do the detailed work of standards preparation and distribution.

Regardless of the organizational scheme, those responsible for

standards work are usually expected to advise and assist top management in the formulation of policies relating to standards and their use. They are called upon to draw up procedures for creating new standards or revising old standards, to report on standards practice and evaluate the company program, to act as coordinators and mediators as standards are being developed, to serve as company representatives to technical associations and other standardizing bodies, to provide technical assistance to standards users and to maintain standards manuals and other records.

**Other Contributors to Standardization.**—Individual firms secure significant benefits by conducting their own standardization programs but there is a point at which standardization on a wide scale becomes necessary to prevent wasteful conflict and duplication of effort among competing systems of standards. Certain fundamental standards should be developed in forms that make them universally usable, and mechanisms for coordination of intersecting standards being evolved in separate fields should be provided. The standards activities of governmental departments, trade associations, technical associations and other organizations serve in part to meet national standards needs, but the presence of a specialized standardizing organization which can coordinate the diverse standardization activities of many different types of organizations and promote general acceptance of basic standards can be a strong force for progress.

In the U.S. the American Standards association (A.S.A.), which has over 110 technical organizations and 2,300 companies as members, performs this function. The A.S.A. does not initiate or write standards but provides the means by which national standards can be developed and approved. All groups having substantial concern with a proposal under consideration in an A.S.A. project have the right to representation. The association makes no effort to enforce any standard but relies on the voluntary support of interested groups.

What the A.S.A. does nationally, the International Organization for Standardization (I.S.O.) does internationally. National and international standards are essentially the same and are developed in the same way. However, just as there are fewer industrial than company standards and fewer national than industrial standards, there are fewer international than national standards. Developing, writing and adopting an international standard is difficult because of the breadth of representation and the diversity of needs and viewpoints that must be reconciled.

To say that standardization is one of the most pervasive and crucial of industrial and scientific activities is no exaggeration. Everyone's life is touched continuously by standards directly or indirectly. Scientific research that widens basic knowledge depends on accurate standards for physical constants and properties of materials as does applied industrial research. Companies may buy and sell with clear understanding on both sides of transactions when they negotiate in standard terms. Producers can manufacture articles of uniform quality and operate more efficiently with standardized processes and products. Consumers may buy agricultural products, meat, processed foods, pharmaceuticals, textiles, clothing, house furnishings and appliances with the assurance that they are getting what they pay for and that the goods are safe to use. *See* MASS PRODUCTION. *See* also references under "Standardization" in the Index.

(J. D. Rs.)

**STANDARD OF LIVING**, in popular usage, the kind and quantity of consumer goods available to an individual, family, or entire nation. Those who have a generous supply of such goods are said to have a high standard of living. But in social science the phrase is used in a different sense and there are supplementary concepts. Standard of living does not denote the goods and services actually available but the aspirations or desires of the individual or group, and is confined to wants that generate a strong desire for fulfillment. Because the terms level of living and level of consumption relate to existing conditions—what is experienced in contrast with what is considered essential—many so-called

standard of living studies might more accurately be described as studies of consumption levels. They do, of course, give indirect information about standards since use tends to indicate what is most desired.

A few people undoubtedly have, at least for short periods of time, an excess of some of the things they desire, in which case their level of living is higher than their standard. The standard of others may be higher than their level. Vague, fleeting wants do not constitute a part of the standard, for, as noted above, it relates only to wants that generate a strong drive for fulfillment. Their achievement brings a marked sense of gratification and their continued lack leads to unrest and a sense of frustration.

Standards of consumption affect population growth and long-run labour supply through their effect on the age of marriage and the birth rate. They also affect the total labour supply in the short run in that people weigh the relative merits of more income against more leisure or more direct production for the family; they affect the labour supply in a given occupation insofar as more income and the additional consumer goods thus made possible may compensate for less pleasant work. The existence of the desire for more consumer goods is also important in inducing families to migrate. Standards of living also have a bearing on the business cycle. Forecasters must take into account the extent to which families will cut consumption when their income declines. To what extent will they decrease savings and draw on assets in order to maintain customary consumption? If production rises, will it find a ready market because of desires previously unmet? Or will the additional income go wholly or largely to savings? (See CONSUMPTION.) In the administration of a war economy or other emergency when customary levels of consumption cannot be maintained it is helpful to know where cuts will be least resented, and how best to carry on an information program in order to make clear the need for the shortages and thus minimize unrest and frustration.

The standard of living has long been a matter of major interest to population analysts. Thomas Malthus, in his *Essay on Population* (1798), argued that population growth is determined by means of subsistence. He believed that it was held in check chiefly by starvation, pestilence, and war, all of which were direct results of population pressure on means of subsistence. This view assumed a static standard of living. By the beginning of the 20th century, the decline in the rate of population growth in industrialized countries after decades of rising productivity shifted attention to the effect of a rising standard of living. Then two fears came to be expressed: (1) that families in general would come to place such a high value on material goods for themselves and their children that the birth rate would fall to a point where total population would decline; and (2) that the effect of a high standard of living on the birth rate was especially marked among families with high income; thus, the quality of the population was likely to be adversely affected. An upturn of the birth rate in some western countries after the middle 1930s, however, allayed the first fear. For example, the 1950 census of the United States reported a 53% increase since 1940 in children under 5 years of age, while the total population increased by only 15%.

Policies and programs of the United Nations during the 1960s brought to the forefront once more a consideration of the validity of the Malthusian doctrine. Among the nations of the world high birth rates occur where the level of consumption is low, and where death rates are high. The value system of these societies tends to stimulate high birth rates. Only thus can the population be maintained in the face of high death rates. Experience indicates that industrialization brings a reduction in mortality before a decline in the birth rate. To what extent is a decline in the birth rate dependent on a rising standard of living? What is the process of bringing this about? There are no clear-cut answers, in spite of the experience in western countries with falling birth rates which resulted, in part, from a rising standard of living.

Standards of living of individuals are a dominant driving force in a society. There are, in addition, social standards of living which are the basis of many types of policies. The levels of consumption provided those in prison or on relief are, for example,

an expression of a society's minimum standard for its members. Social standards are implicit in minimum wages, unemployment benefits, public old age pension systems, family allowances and the provision of various goods from public funds. In addition to individual and social standards there are normative standards provided by specialists which are used as yardsticks in evaluating consumption.

**STANDARDS, NATIONAL BUREAU OF.** Since its founding in 1901, the National Bureau of Standards has become the chief U.S. government agency for fundamental research in physics, chemistry, metallurgy, and engineering sciences. It functions as a national physical science laboratory to improve physical measurement, determine physical constants and critical properties of materials, and render technical services to other government agencies. It is responsible for maintaining and developing the country's standards of measurement. It constructs physical standards, tests and calibrates measuring apparatus, improves measuring techniques, and promotes better state laws, industrial practices, and international agreements concerning standards. The bureau also investigates the chemical nature of materials, high- and low-temperature phenomena, radiation, atomic and molecular structure of chemical elements, electronics, radio transmission, building materials, and metallurgy. These investigations are instrumental in advancing basic science, industrial technology, merchandising, communication, public health and safety, and space exploration.

Federal responsibility for standard weights and measures dates back to the nation's founding when the U.S. Constitution gave Congress the power to fix such standards. While serving as secretary of state, both Thomas Jefferson (1790) and John Quincy Adams (1821) made elaborate reports on weights and measures. Since Congress for many decades did not legislate in this field, federal action took place primarily by executive order. Most of the early efforts to determine standards were made by the Treasury Department because it operated the customs houses and the Coast Survey, which needed accurate standards. Since the latter agency possessed the needed personnel and instruments, it assumed responsibility for weights and measures until the National Bureau of Standards was created in 1901. The first superintendents of the Coast Survey (later called the Coast and Geodetic Survey), Ferdinand Rudolph Hassler, a Swiss mathematician and engineer, and Alexander Dallas Bache, noted American educator and scientist, acted as superintendent of the Office of Weights and Measures. In the 1830s this office adopted standard weights and measures and began making copies of them for the customs houses, individual state governments, and sometimes foreign governments.

The work of this office gradually became inadequate for the growing needs of industrial technology, especially when the electrical industry developed. With the need for electrical standards, pressure mounted in the 1890s to reorganize and expand the agency. Great Britain and Germany had national physical laboratories and were ahead of the United States in developing standards. Aided by leading scientific societies, government scientists drafted a bill for an expanded standards laboratory. The organic act of March 3, 1901, that created the National Bureau of Standards made it responsible for the custody, preparation, and testing of standards, the solving of problems involving standards, and the determination of physical constants and properties of materials. It was empowered to assist other government agencies in matters of standards and, for a fee, to give such aid to scientific societies, business firms, and universities. The act placed the bureau in the Treasury Department, but in 1903 it was shifted to the new Department of Commerce and Labor. After this department was divided into a Department of Labor and a Department of Commerce, the Bureau of Standards was assigned to the

Department of Commerce along with various other scientific agencies. In 1965 the Weather Bureau, the Coast and Geodetic Survey, and the Central Radio Propagation Laboratory of the National Bureau of Standards were combined to form the Environmental Science Services Administration.

The early scientific divisions of the Bureau of Standards included electricity; weights and measures; thermometry, pyrometry, and heat measurement; optics; chemistry; and engineering instruments and materials. Divisions were soon created for metallurgy and for structural, engineering, and miscellaneous materials. When experimentation in radio communications became important, Congress in 1916 appropriated funds for a radio laboratory (see above). In the 1920s, under Secretary of Commerce Herbert Hoover, the bureau greatly increased its research activities that were directly beneficial to industry and fostered commercial standardization to eliminate industrial waste and promote efficiency. An aeronautical division was created, and trade associations supported research associates at the bureau for work on technical problems of industry. This practice reached significant levels in the 1950s.

Although the bureau retrenched during the depression, it mushroomed during and after World War II. It developed the proximity fuze (see AMMUNITION, ARTILLERY) and took part in the nuclear research that led to the development of the atomic bomb. In the early 1950s it handled extensive developmental work on military ordnance and missiles until this work was transferred to the military services. It also increased its work on standards and physical properties, especially in electronics, nuclear physics, data-processing systems, building technology, cryogenic engineering, and radio propagation. It endeavoured to develop a precise, interrelated system of highly accurate measures of length, time, and mass based on specific atomic constants. It executed research for numerous government agencies on technical problems, and prepared specifications and tests required for materials purchased by the government. Its work advanced basic science, benefited many industries, and contributed to health, safety, and national defense. It investigated scientific and technological problems of space exploration, including radiation, instrumentation, new alloys and synthetic materials, and behaviour of materials under extreme conditions of temperature, speed, and pressure.

The bureau concentrates much of its research in physics, chemistry, and engineering in Washington, D.C., where it has divisions for electricity and electronics, optics and metrology, heat, atomic and radiation physics, chemistry, mechanics, organic and fibrous materials, metallurgy, mineral products, building technology, applied mathematics, and data-processing systems. It also has technical offices of weights and measures, basic instrumentation, and technical information. The bureau's laboratory at Boulder, Colo., is a major installation with divisions for cryogenic engineering, radio propagation physics, radio propagation engineering, radio standards, and radio communication and systems. The bureau has several field stations for testing and developmental purposes, including the testing and monitoring of radio frequencies and propagation. When it took over the functions of the Office of Technical Services the bureau established a Clearinghouse for Federal Scientific and Technical Information. The bureau divided its activities into four institutes: Institute for Basic Standards, Institute for Materials Research, Institute for Applied Technology, and Central Radio Propagation Laboratory.

In addition to special reports and nonperiodical publications, the bureau publishes its research findings in three periodicals: the *Journal of Research* (issued monthly until 1959, thereafter quarterly in four separate sections—Physics and Chemistry, Mathematics and Mathematical Physics, Engineering and Instrumentation, and Radio Science) and the monthly *Technical News Bulletin* and *Central Radio Propagation Laboratory Ionospheric Predictions*.

See A. Hunter Dupree, *Science in the Federal Government* (1957); Gustavus A. Weber, *The Bureau of Standards* (1925). (F. G. H.)

**STANDISH, MYLES** or **MILES** (c. 1584–1656), American colonist and military leader, was born in Lancashire, Eng. He became a soldier and fought in the Netherlands, where he probably

met the English religious exiles now known as the Pilgrims. He sailed with them to America in the "Mayflower" in 1620 and served as their military leader when they established Plymouth in New England. He was the first to learn the language of the local Indians and led several expeditions against hostile tribes. He went to England on business for the colony in 1625–26, and in 1627 was one of the leaders of the group in the colony that bought out the London investors (merchant adventurers). In 1628 Standish helped to break up the colony of Thomas Morton (q.v.) at nearby Merry Mount when it proved too unpuritanical to suit Plymouth. He also served as assistant governor and as treasurer of the colony (1644–49). He moved to Duxbury in 1632 and died there in 1656. After his wife died during the first winter at Plymouth, he married again in 1624.

A short, stocky man with red hair, referred to as "Captain Shrimp" by Morton, Standish was known for his quick temper. There is no historical evidence for the story told in Longfellow's poem, "The Courtship of Miles Standish," that he asked John Alden to propose marriage for him to Priscilla Mullins.

(B. Sm.)

**STANFORD, AMASA LELAND** (1824–1893), U.S. senator from California and one of the builders of the first transcontinental railroad, was born in Watervliet, N.Y., March 9, 1824. Having prospered in the retail trade in Sacramento, Calif., in 1861 he became president of the Central Pacific Railroad, which built eastward to a junction with the Union Pacific at Promontory Point, Utah, in 1869. Stanford, a Republican, served as Civil War governor of California (1861–63) and was elected to two terms in the U.S. Senate. In memory of their only child, who died at 15, Stanford and his wife, Jane, founded Leland Stanford Jr. University (commonly known as Stanford University) in 1885, granting 9,000 ac. on the San Francisco peninsula and an endowment of \$21,000,000. Stanford died June 21, 1893.

See George T. Clark, *Leland Stanford* (1931).

(P. C. A.)

**STANFORD, SIR CHARLES VILLIERS** (1852–1924), Irish composer, conductor, and teacher who had a wide influence on the younger British composers of his time, was born in Dublin on Sept. 30, 1852. He studied the organ at Trinity College, Dublin, and from 1870 at Queen's College, Cambridge. Between 1874 and 1877 he studied with Karl Reinecke in Leipzig and with Friedrich Kiel in Berlin. In 1883 he was appointed professor of composition at the Royal College of Music, London, and in 1887 professor of music at Cambridge. Ralph Vaughan Williams, Sir Arthur Bliss, and Gustav Holst were among his pupils. Between 1885 and 1902 he was conductor of the London Bach Choir and from 1901 to 1910 of the Leeds Triennial Festival. He was knighted in 1901.

Stanford was a prolific composer in all spheres but was especially known during his lifetime for his orchestral works, his songs, and his operas. He adopted the broad features of the late-19th-century romantic style into which he introduced Irish folk song elements. His first opera, *The Veiled Prophet of Khorassan*, was given in German as *Der verschleierte Prophet* at Hanover in 1881, and this was followed by *Savonarola*, given at Hamburg in 1884. He developed his Irish manner in *Shamus O'Brien*, performed in London in 1896. *Much Ado About Nothing*, based on Shakespeare, and *The Critic*, based on Sheridan, were given in London respectively in 1901 and 1916, but *The Travelling Companion*, based on a story of Hans Andersen, was not performed until 1925, at Liverpool. Stanford's orchestral works include seven symphonies and five *Irish Rhapsodies*. Among his choral works are *Songs of the Sea* and *Songs of the Fleet*, both on poems of Henry Newbolt. His lyrical style is best seen in his songs, which include settings of Keats, Shelley, Tennyson, and Heine. His pedagogical works are *Musical Composition* (1911) and, with C. Forsyth, *A History of Music* (1916). He died in London on March 29, 1924.

See H. P. Greene, *Charles Villiers Stanford* (1935).

**STANFORD UNIVERSITY** is near Palo Alto, Calif., in the Santa Clara Valley. It was founded in 1885 as the Leland Stanford Jr. University by Leland Stanford (1824–93) and his wife, Jane Lathrop (1825–1905), as a memorial to their only child, Leland Stanford, Jr., who died in 1884 at the age of 15. The

founder was governor of California in 1861-63 and U.S. senator from 1885 until his death. The doors were opened in 1891 to 559 students. The university campus consists of Stanford's former Palo Alto farm, comprising about 9,000 ac. The founders also established an endowment of \$21,000,000.

The buildings, conceived by Frederick Law Olmsted, the creator of Central Park in New York City, are of soft buff sandstone in a style similar to the old California mission (Moorish-Romanesque) architecture, being long and low with wide colonnades, open arches, and red-tiled roofs.

Inner and outer quadrangles of buildings, centring on Stanford Memorial Church, form the original group of classrooms and offices. Buildings later erected in adjoining areas include the art gallery, the theatre, the music auditorium, main and undergraduate libraries, the Hoover Institution on War, Revolution, and Peace, the museum of art and archaeology, the medical centre, gymnasiums, laboratories of physics, chemistry, and engineering, the computer centre, Stanford University Press, alumni headquarters, the student activities centre, the student health centre, international house, and the faculty club. Laurence Frost Amphitheater seats 8,000.

The Hopkins Marine Station is maintained by the University at Pacific Grove on the Bay of Monterey. It operates the "Te Vega," a 135-ft. schooner equipped for biological oceanographic studies by scientists and graduate students.

As part of its General Studies Program, Stanford maintains branch campuses in France, Italy, Germany, Austria, and England. About half of its undergraduates study overseas for six-month periods. Advanced study centres are maintained in Japan, Formosa, and several other countries.

The departments of the university are organized into schools of law, medicine, education, engineering, business, earth sciences, and humanities and sciences. Enrollment reached 11,000 in the 1960s.

In 1921 the Food Research Institute of Stanford University was organized, with the help of the Carnegie Corporation of New York. The Hoover Institution, founded by Herbert Hoover during World War I, contains more than 1,000,000 printed and manuscript items dealing with World Wars I and II, revolutionary movements of the 20th century, and international relations.

The Stanford Linear Accelerator Center was established in 1961 when Congress appropriated \$114,000,000 for construction on the campus of an accelerator 2 mi. long under contract with the Atomic Energy Commission. The Stanford Medical Center, completed on the campus in 1959, includes eight buildings, three of them the Palo Alto-Stanford Hospital of 438 beds. A 1,000-bed Veterans Administration Hospital is also on Stanford lands.

Five thousand of the university's acres were set aside for the educational campus and the remaining 4,000 ac. for residential, light industrial, commercial, and professional uses on a leasehold basis. There is an arboretum of about 300 ac.

The university campus was zoned, and space was reserved for an extension of the residence hall system for men and for women, together with the athletic fields. The large extent of the campus made it possible to develop athletic fields of considerable size and diversity, including an 18-hole golf course and a 90,000-seat stadium. Space was reserved also for experimental and ornamental purposes and as residence sites for faculty. David Starr Jordan (q.v.) was the first president. (R. L. W.; P. C. A.)

**STANHOPE, CHARLES STANHOPE, 3RD EARL** (1753-1816), English statesman and scientist, an eccentric with a touch of genius, who made a name for himself not only as a thoroughgoing radical but also as an experimental scientist, was born in London, Aug. 3, 1753, and educated at Eton and Geneva. As Lord Mahon, he was M.P. for Chipping Wycombe from 1780 until his succession to the peerage in 1786. He opposed the American war, but also the Fox-North coalition. In 1783 he declined office under William Pitt, whose sister he had married in 1774, but remained his supporter until the French Revolution. He sympathized with the aims of the French republicans, loved to call himself "Citizen Stanhope," and was chairman of the Revolution Society, one of the popular societies advocating the democratiza-

tion of Parliament. He opposed the war with France, and deprecated interference with its internal affairs. Being "in a minority of one" in the House of Lords he seceded from Parliament for five years (1795-1800).

Stanhope's inventions included the printing press and the microscopic lens which bear his name, two calculating machines, a steam carriage, and a steamship for conveying coal from Newcastle to London, which, however, said Lord Holland, "would have consumed its cargo before it could have reached its destination." He made a new kind of cement, much more durable than ordinary mortar, and artificial slates or tiles composed of tar, chalk, and fine sand. He projected a canal to link up his Devonshire estate at Holsworthy with the Bristol Channel, and experimented with new methods of raising and lowering the barges. His writings include *Considerations on the Means of Preventing Fraudulent Practices on the Gold Coin* (1775), *Principles of Electricity* (1779), *A Letter to Burke, Containing a Short Answer to His Late Speech on the French Revolution* (1790), and pamphlets supporting Fox's libel bill (1792) and opposing the union with Ireland (1800). Lady Hester Stanhope was his eldest daughter by his first wife. He died at Chevening, on Dec. 15, 1816.

See G. P. Gooch, *Life of Charles, 3rd Earl Stanhope* (1914). (A. AL.)

**STANHOPE, JAMES STANHOPE, 1ST EARL** (1673-1721), English soldier and statesman, was a grandson of the first earl of Chesterfield, and eldest son of Alexander Stanhope, a diplomatist, from whom he acquired both strong Whig principles and a knowledge of languages and diplomacy. He was born in Paris and was later naturalized as a British subject. In 1691 he went to Italy to study the art of war under the duke of Savoy. Subsequently he served in Flanders, Spain and Portugal under such distinguished generals as Marlborough and the duke of Ormonde. He accompanied the earl of Peterborough to Spain in 1705, supporting his plan to divert the campaign to Italy, and distinguished himself in the attack on Barcelona (see SPANISH SUCCESSION, WAR OF THE). In 1706 as minister to the titular Charles III of Spain, he advocated an aggressive strategy, but allied dissensions led to defeat at Almanza (1707). Commander in chief in Spain in 1708, Stanhope captured Port Mahon to provide a winter anchorage for the Mediterranean fleet, and in 1710 his bold methods won victories at Almenar and Saragossa. Stanhope, however, occupied Madrid instead of excluding from Spain the French reinforcements which, under the duc de Vendôme, defeated and captured him at Brihuega (Dec. 1710). The Tory government in England did little for the release of so pronounced a Whig, and Stanhope did not return until August 1712.

Stanhope had become M.P. for Newport (Isle of Wight) in 1701, and occupied the duke of Somerset's seat at Cockermouth, 1702-13. In 1710 he was among the chief managers of the Sacheverell trial (see SACHEVERELL, HENRY), and the Whigs strove furiously to get him elected in his absence for Westminster at the ensuing general election. He accepted the Utrecht treaty once it was signed, but contrived to defeat the projected Tory commercial treaty with France. Stanhope rebuffed Tory accusations of speculation in Spain, and was now so prominent in opposition that when defeated at Cockermouth in 1713, he was overwhelmed with offers of seats and chose to sit for Wendover; the opposition moreover gave him supreme charge of the secret military measures designed to secure the Hanoverian succession.

To the general surprise, Stanhope was made southern secretary on the accession of George I, sharing with Robert Walpole the leadership of the house of commons. It was in foreign policy, however, that Stanhope revealed his genius. He at once renounced the Tory policy of alliance with France which had not ended with the Austro-Spanish conflict, in favour of the Whig tradition of agreement with the emperor, and, if necessary, war against France. By prolonged negotiation Stanhope persuaded the emperor to concede a Barrier treaty to the Dutch in 1715, which foreshadowed the ending of British diplomatic isolation by the treaty of Westminster with the emperor and Dutch in 1716. He also secured a very favourable commercial treaty with Spain in May 1716. The regent, the duke of Orléans, now hoped that Britain would support

his succession to the French crown should Louis XV die; Stanhope was at first very hostile to his overtures, but was won to them in 1716 by Russian threats to the German interests of Hanover, and by a projected Russo-Swedish *rapprochement* which might intensify Swedish intrigues with the English Jacobites. The Triple alliance (1717) with France and the Dutch minimized foreign support for the Jacobites, and gained for England the valuable diplomatic influence and organization of France in northern Europe. Stanhope now sought to reconcile Spain and the emperor by offering the succession to the Italian duchies to Don Carlos, the queen of Spain's son, and compensating the emperor by exchanging his island of Sardinia for Sicily, then held by Savoy. In 1718 Stanhope brought the emperor into the Quadruple alliance to impose peace on these terms, terms which Spain accepted under duress in 1720. Stanhope's peace plan was not completely fulfilled for a decade after his death, but his French alliance made Britain for 15 years the diplomatic arbiter of the west, and earned him a viscountcy in 1717 and an earldom in 1718.

In the north Stanhope was less successful, for England was at loggerheads not only with Sweden (for its attacks on English shipping and Jacobite conspiracies) and Russia (for its incursions into Germany), but also with its ally France which desired to save the German territories of Sweden, coveted by Hanover and its allies, by sacrificing to Russia Sweden's Baltic lands from which the British navy derived essential stores. The king and the Hanoverian ministers were tempted to divert the fleets (sent to the Baltic every year after 1715 to protect British shipping) to illegal Hanoverian purposes, thus provoking the resignation of the Townshend-Walpole connection from the government in 1717; Stanhope was now chief minister. On the death of Charles XII in 1718, he sought favourable terms from Sweden and offered to defend it against Russia by a coalition of the other Baltic powers. To form this coalition he himself broke the resistance of the Hanoverian ministers to an alliance with Prussia in 1719, and in the following year finally ended Hanoverian interference in English affairs. Under his direction Sweden was reconciled with all its Baltic neighbours except Russia, but in 1721, after Stanhope's death, Peter the Great was able to dictate his own terms to Sweden.

Stanhope had no fixed home in England until after he was 40, and never rivaled Walpole's grasp of domestic politics, but as secretary of state and first lord of the treasury (1717-18) he held a leading role in home affairs. He co-operated cordially with Sir Robert Walpole and Lord Townshend in suppressing the Jacobite revolt of 1715, softened Townshend's fall in the winter of 1716-17, and carried through the comprehensive financial scheme introduced by Walpole in 1717. Always the champion of religious minorities, he repealed the Occasional Conformity and Schism acts in 1718, but further concessions to Protestant dissenters and Roman Catholics were prevented by the split in the Whig party. In 1719 he unreservedly backed the earl of Sunderland's plan to reunite the Whigs by promoting the Peerage bill to fix the number of peers, state control of the universities and the repeal of the Septennial act which he himself had passed in 1716. By defeating the first of these measures, however, Walpole ensured both the abandonment of the rest, and his own return to office. The last year of Stanhope's life was darkened by the South Sea company scandal (see SOUTH SEA BUBBLE), and, though in no way implicated, he was about to retire from politics into Marlborough's place of captain general when in Feb. 1721 he died of a blood vessel burst in anger during a South Sea debate in the house of lords.

See the standard life of Stanhope, B. Williams, *Stanhope: a Study in Eighteenth-Century War and Diplomacy* (1932). (W. R. Wb.)

**STANISLAVSKI, KONSTANTIN SERGEEVICH ALEKSEEV** (1863-1938), great Russian actor, producer, and theoretician of the art of acting, was born in Moscow on Jan. 17 (new style; 5, old style), 1863. His father, S. V. Alekseev, was a wealthy industrialist, and his grandmother, a French actress. He began his acting career at 15 in the Alekseev Circle, an amateur group consisting mostly of the members of his family. In December 1888 he founded the Society of Art and Literature, one of Moscow's most popular amateur theatrical companies. In June

1897 V. I. Nemirovich-Danchenko (*q.v.*), playwright and director of the drama school of the Moscow Philharmonic Society, invited him to form a new theatre. They drew up the program of the Moscow Art Theatre (*q.v.*), Nemirovich-Danchenko undertaking responsibility for literary and administrative matters and Stanislavski for staging and production. Stanislavski scored his first great success as producer with A. P. Chekhov's *The Seagull*, in December 1898, and through his genius the Moscow Art Theatre became world famous. Chekhov wrote *The Three Sisters* (1901) and *The Cherry Orchard* (1903) specially for it, and in 1923 Stanislavski toured the United States with it. Stanislavski's fame, however, rests chiefly on his theory of acting, his celebrated system or method: "What is important to me is not the truth outside myself, but the truth within myself . . . the truth of my attitude towards anything on the stage, towards my partners who represent other characters in the play and towards their thoughts and feelings." (*My Life in Art*; Theatre Arts Books, New York, 1924; renewed 1952 by Elizabeth Reynolds Hapgood.) Other writings include *An Actor Prepares* (Eng. trans. 1936) and *Building a Character* (Eng. trans. 1949). He died in Moscow on Aug. 7, 1938. See also ACTING, DIRECTION AND PRODUCTION: *Acting: Stanislavski*.

See D. Magarshack, *Stanislavsky: a Life* (1951). (D. Mx.)

**STANISLAW, SAINT** (?1030-1079), bishop of Cracow from 1072, murdered by King Boleslaw II (*q.v.*), was the first Pole to be canonized (1253) and is a patron saint of Poland. He was born at Szczepanow, near Tarnow, on July 26, 1030, into a Polish noble family, and was educated at Gniezno, the Polish metropolitan see, and probably also in Paris. Elected bishop of Cracow in 1072, he was accused in 1079 of treason against his sovereign. The royal court—in which the head of the Polish Church, the metropolitan of Gniezno, participated—found Stanislaw guilty and sentenced him to the loss of his limbs. As the knights who had been ordered to execute the sentence hesitated, King Boleslaw slew the bishop himself on April 11 in the St. Michael chapel in Cracow.

This tragedy remains an unsolved mystery. Polish historians of repute believe that the bishop participated in a Bohemian-German plot designed to remove the able King Boleslaw and replace him by his indolent brother, Wladyslaw Herman. Polish Catholic writers describe the execution as a contemptible act of revenge against a saintly bishop who had excommunicated a cruel and licentious king. St. Stanislaw's feast is May 8 in Poland, May 7 elsewhere.

Stanisława* (1953); K. Lanckorońska, "W sprawie zatargu między Bolesławem Śmiałym a św. Stanisławem," in *Teki Historyczne*, London IX (1958); *The Cambridge History of Poland*, vol. i (1950).

(K. Sm.)

**STANISLAW I** (STANISLAW LESZCZYŃSKI) (1677-1766), twice elected king of Poland and finally duke of Lorraine and Bar. He was born in Lvov on Oct. 20, 1677, the only son of a Poznanian magnate. His education was completed by travels in Western Europe. His first election as king of Poland (July 12, 1704) was procured by the Swedish king, Charles XII, in the first phase of the Northern War (*q.v.*), after Charles had enforced the deposition of King Augustus II (Frederick Augustus I of Saxony). After the defeat of Charles at Poltava (1709), Stanislaw left Poland and settled at Wissembourg, in Alsace, while Augustus II recovered the kingdom.

In 1725 Stanislaw's daughter Marie was married to Louis XV of France; and in 1733, after Augustus II's death, France supported his candidature to the Polish throne. Stanislaw went in disguise to Warsaw and, on Sept. 12, 1733, was elected king by an overwhelming majority of the Diet. The War of the Polish Succession (*q.v.*) then broke out, as Russian armies entered Poland to annul his election. Under Russian pressure, a small minority in the Diet accepted the Saxon elector Frederick Augustus II as king of Poland, with the style of Augustus III, on Oct. 5, 1733. Stanislaw had to take refuge in Gdansk, which his enemies then besieged. Before the capitulation of the city he escaped to Königsberg in Prussia, whence he directed the guerrilla warfare of his partisans

in Poland. The preliminary peace between France and Austria (1735) and the definitive Peace of Vienna (1738) decided that Augustus III was to remain on the throne, and that Stanislaw, retaining his royal title, was to have Lorraine and Bar for life.

In Lorraine, Stanislaw proved himself a good administrator and a promoter of economic development. His court at Lunéville became famous as a cultural centre. He founded an Academy of Science at Nancy and a military college. His authorship of the "Free Voice to Make Freedom Safe," published in 1749 and outlining constitutional reforms for Poland, is controversial. He died at Lunéville on Feb. 23, 1766. There are editions of his letters to his daughter Marie (1901), to the kings of Prussia (1906), and to Jacques Hulin, his minister at Versailles (1920).

**STANISLAW II** (STANISLAW AUGUST PONIATOWSKI) (1732-1798), the last king of independent Poland, was born at Wolczyn, near Brzesc (Brest), in Polesie, on Jan. 17, 1732, the sixth child of Stanislaw Poniatowski, palatine of Mazovia, and Princess Konstancja Czartoryska. After careful education he traveled in England, France, Holland, and Germany. In 1757, during the Seven Years' War (*q.v.*), he was sent by the Czartoryskis (*see* CZARTORYSKI) to St. Petersburg to obtain Russian support for their plans to reform the state and to dethrone King Augustus III (Frederick Augustus II of Saxony). At first he was officially on the staff of the British embassy, but later he was appointed Polish envoy to Russia. Without doing much for the Czartoryskis, he consolidated his personal position in St. Petersburg, becoming a favourite of the future empress Catherine II (*q.v.*).

With Catherine's support, Poniatowski was elected king of Poland on Sept. 7, 1764. He tried to strengthen the royal power, to modernize the state administration, and to improve the parliamentary system; but his reforms were opposed by a group of magnates, and Catherine II, by threatening him with dethronement (1768), forced him to drop his plans. He was then faced with the Confederation of Bar (*q.v.*), which proclaimed an interregnum, thus making the king even more dependent on Russia.

In 1772 Russia, Prussia, and Austria carried out the first partition of Poland (*see* POLAND: *History*). The Polish king in vain appealed to the Western powers. During the *Sejm* (Diet) of 1772-75 he tried to obtain the consent of the partitioning powers for constitutional reforms. Eventually his power was further limited, and he became president of the Permanent Council (a government elected every two years by the *Sejm*). Between 1776 and 1788, though he was severely handicapped by the magnates' opposition and by Russian supervision, he managed to strengthen his power to some degree. With his support the Commission of National Education was formed; and he invited artists to his court, made a famous collection of paintings, reconstructed the royal castle in Warsaw and built a fine suburban residence—Lazienki.

During the Four Years' *Sejm* (1788-92), the king took an active part in its attempt at reform. This led to the voting of the constitution of May 3, 1791. To oppose the new constitution, the Confederation of Targowica was formed, with Russian backing; and as the Russians invaded Poland the king joined the confederation. He participated in the captive *Sejm* at Grodno (1793), which had to assent to the second partition of Poland. During the Polish insurrection of 1794, Tadeusz Kosciuszko (*q.v.*) overrode all royal authority; and after the defeat of the insurrection the king abdicated, at Grodno on Nov. 25, 1795. In semicaptivity in St. Petersburg, he died on Feb. 12, 1798. His *Mémoires*, in two volumes, were published by S. M. Goryaninov (1914-24).

**BIBLIOGRAPHY.**—R. Nisbet Bain, *The Last King of Poland* (1909); J. P. Palewski, *Stanislas-Auguste Poniatowski* (1946); J. Fabre, *Stanislas-Auguste Poniatowski et l'Europe des lumières* (1952); S. Mackiewicz, *Stanisław August* (1953); A. Zahorski, *Stanisław August, polityk* (1959). (A. Za.)

**STANLEY**, the name of a famous English family which has held the title of earl of Derby since 1485. It derives its name from Stanley, near Leek, in Staffordshire. The first known ancestor is ADAM DE STANLEY (fl. mid-12th century). His son WILLIAM

received Stanley and half of Balterley, in Staffordshire, from his cousin Adam de Audley. William's descendant WILLIAM acquired the hereditary forestership of Wirral through his marriage in 1282 to Joan, daughter and coheir of Philip de Baumville.

This William's great-grandson WILLIAM married Margery, daughter of William de Hooton, and was the ancestor of the Stanleys (afterward Erringtons) of Hooton, whose baronetcy, created in 1661, became extinct in 1893. His brother JOHN (d. c. 1414) was lord deputy in Ireland (1386-88) and the king's lieutenant in Ireland (1399-1401, 1413-14). In 1406 he was granted the Isle of Man in fee. By his marriage (c. 1385) to Isabel Lathom, heiress of a great estate in Lancashire, he founded his family's fortunes. John's grandson THOMAS (c. 1405-1459) was the king's lieutenant in Ireland (1431-37) and in 1456 was summoned to Parliament as Baron Stanley. Thomas's eldest son, also THOMAS (c. 1435-1504), 2nd baron, placed the crown on the head of Henry VII on the battlefield of Bosworth (Aug. 22, 1485). Created earl of Derby (October 1485), he was the ancestor of the Stanley earls of Derby (*q.v.*).

The 1st baron's second son WILLIAM (d. 1495) of Holt gave crucial support to Henry VII at Bosworth. He was implicated in the plot to put Perkin Warbeck on the throne and was beheaded, but it is probable that the king's desire for William's great wealth was responsible for his execution. JOHN, the third son of the 1st baron, married Elizabeth, daughter and heir of Sir Thomas Weever. John's grandson THOMAS (d. 1672) was made a baronet in 1660 and his descendant JOHN THOMAS (1766-1850), 7th bart., was created Baron Stanley of Alderley in 1839. His son EDWARD JOHN (1802-1869), 2nd baron, was president of the Board of Trade (1855-58) and postmaster general (1860-66). He was created Baron Eddisbury of Winnington in 1848. His third son, EDWARD LYULPH (1839-1925), 4th baron, inherited the barony of Sheffield of Roscommon in 1909 from a kinsman. This Edward's grandson, EDWARD JOHN (1907-) is the present holder of the titles.

**STANLEY, SIR HENRY MORTON** (1841-1904), Welsh explorer of Africa, a naturalized American who later resumed his British nationality, is popularly famous for his relief of David Livingstone in 1871, but his true importance lies in his discovery and development of the Congo. He was born on Jan. 28, 1841, at Denbigh, North Wales, the illegitimate son of John Rowlands and Elizabeth Parry, and was registered as John Rowlands. His mother left him to the care of her father, Moses Parry, and he grew up partly in the charge of reluctant relatives and partly in the St. Asaph workhouse, where he suffered from the severity of the workhouse master, James Francis. He acquired a reasonable education at St. Asaph, developed a strong religious faith and learned to value order and cleanliness; but the humiliations of institutional life left deep marks on his character, as did his mother's continued neglect. At the age of 15 he ran away from the workhouse and his escape was followed by an unhappy interlude of dependence on his mother's relations which only ended when he sailed from Liverpool as a cabin boy to New Orleans, La., where he landed in 1858.

There Rowlands met Henry Morton Stanley, a benevolent merchant who took charge of him, gave him his own name and declared his intention of providing for him. Although Stanley died abroad soon afterward, leaving his protégé once more alone in the world, his kindness gave a new direction to the boy's life; henceforth young Stanley felt that at least one person had loved him and believed in him, and in his own prosperous middle age he too adopted a son.

For some years Stanley led a roving life: a soldier in the American Civil War, a seaman in merchant ships and in the federal navy, a journalist in the early days of frontier expansion—he even included a trip to Turkey. Twice he visited his mother in Wales only to encounter the same indifference she had shown since his birth.

In 1867 Stanley offered himself to James Gordon Bennett Jr. of the *New York Herald* as special correspondent on the British Abyssinian campaign, and was first with the news of the fall of Magdala in 1868. He was in Madrid covering the Spanish Civil

War for the *New York Herald* when, in 1869, Bennett summoned him to Paris and commissioned him to "find Livingstone."

**Relief of Livingstone, 1869-73.**—Little had been heard of Livingstone after he left for the interior of Africa in 1866 to explore the central African lakes and to ascertain the source of the Nile, but he was thought to be in the neighbourhood of Ujiji on Lake Tanganyika. Bennett instructed Stanley to travel to Africa by way of Egypt (for the opening of the Suez canal), Syria and Palestine, and it was not until Jan. 6, 1871, that he reached Zanzibar. Intent on a "scoop," Stanley was secretive with the Zanzibar authorities, including the British consul, Sir John Kirk, who was responsible for Livingstone's supplies. Stanley set out for the interior on March 21, and with a well-equipped caravan forced his way through a countryside disturbed by fighting and stricken with sickness. He reached Ujiji in November, where he found Livingstone, greeting him with the famous words "Dr. Livingstone, I presume." Together they explored Lake Tanganyika, proving that the Rusizi river flowed into and not out of the northern end of the lake and so could not be the Nile as had been suggested by those geographers who doubted J. H. Speke's choice of Lake Victoria as the main source. Stanley arrived back in Zanzibar in May 1872, leaving Livingstone to pursue his search for the Nile further west in the region of what, as Stanley himself was later to prove, was the Congo. Stanley was not well received in England, where it was felt that he had anticipated Livingstone's sponsors and the feeling against him was increased by the knowledge that Livingstone had been in real need of relief and that his own friends had failed where a stranger had succeeded. In the same year (1872) Stanley published his story in *How I Found Livingstone*.

Stanley did little to conciliate either Sir John Kirk or Sir Henry Rawlinson, president of the Royal Geographical society; nevertheless, the society awarded him their Patron's medal for 1873. He addressed the British association at Brighton in October, and he was received by Queen Victoria who gave him a gold snuffbox and her thanks for his services. In 1873 Stanley went to Ashanti as war correspondent for the *New York Herald* and in 1874 he published *Coomassie and Magdala: the Story of Two British Campaigns in Africa* describing his experiences there and in Abyssinia.

**Through the Dark Continent (1874-77).**—Livingstone died in 1873, and Stanley resolved to take up the exploration of Africa where he had left off. The problem of the Nile sources and of the position and size of the central African lakes had been only partly solved by Livingstone, Sir Richard Burton, Speke and Sir Samuel Baker, and Stanley secured financial backing from the *Daily Telegraph* and the *New York Herald* for an expedition to Africa. Well manned and provisioned and with three white companions, Stanley left Zanzibar on Nov. 11, 1874, and headed for Lake Victoria. His visit to King Mtesa of Buganda during 1875 paved the way for the admission of Christian missionaries in 1876 and for the eventual establishment of a British protectorate. Circumnavigating Lake Victoria in his boat, the "Lady Alice," Stanley confirmed Speke's estimate of its size and importance. Skirmishes with suspicious natives on the lake shore, and especially the fight at Bumbireh which resulted in a number of casualties, gave rise to much criticism in England of this new kind of traveler with his journalistic outlook and forceful methods. On this voyage were sown the seeds of Stanley's later unpopularity and of the rough political campaigns when he was heckled as a "man of blood." His claim to be acting in self-defense was put forward in aggressive terms which did not reassure public opinion in England.

Stanley was prevented by tribal unrest from investigating Lake Albert, and he turned south to Lake Tanganyika, which he also circumnavigated, finding no outlet to connect it with Lake Albert and the Nile system.

By the end of 1876 Stanley was ready for what he called "the grandest task of all"—the identification of the Lualaba river which Livingstone had hoped might be the Nile but thought more likely to be the Congo. In 1876 the expedition reached Nyangwe, Livingstone's furthest point north on the Lualaba, and set off

down the river reinforced by Tippoo Tib, the leading Arab trader of the region.

When the Arabs turned back at the limit of their trading area, Stanley launched the "Lady Alice" and sailed down the unknown river to the lake he called Stanley pool; from there he marched overland to the sea which he reached on Aug. 12, 1877. His three white companions and half his Africans were dead, but he had traced the Congo. Stanley described this tremendous journey in *Through the Dark Continent* (1878).

**The Founding of the Congo Free State (1879-84).**—Failing to interest the British government in developing the Congo, Stanley accepted the invitation of King Leopold of the Belgians to lead an expedition there under the auspices of the Comité d'Études du Haut Congo, later merged in Leopold's International association for exploring and developing Africa. From Aug. 1879 to June 1884 Stanley was in the Congo basin where he made a road from the lower Congo up to Stanley pool, launched steamers on the upper river and built a chain of stations. His perseverance in the face of difficulties earned him from his men the nickname of Buta-Matari—the "rock breaker." The Berlin conference of 1884-85, which Stanley attended, recognized the Congo Free state under the sovereignty of King Leopold, representing the International association.

**Relief of Emin Pasha (1887-1889).**—Stanley's last expedition in Africa was for the relief of Mehmed Emin Pasha, governor of the Equatorial province of Egypt. Emin had been cut off by the Mahdi revolt of 1882 in the neighbourhood of Lake Albert. Sir William MacKinnon, chairman of the British East Africa company, launched a rescue fund and invited Stanley to lead an expedition. Stanley chose to travel by way of the Congo; he knew the route and relied on Tippoo Tib to supply porters. He left England in Jan. 1887 and, stopping to recruit men in Zanzibar, arrived at the mouth of the Congo in March. The expedition reached the navigable head of the river in June and there, at Yambuya, Stanley left a rear column under Maj. E. M. Barttelot and J. S. Jameson, with orders to await Tippoo Tib's porters and to follow on if these failed to arrive.

Stanley, with Lieut. W. G. Stairs, Capt. R. H. Nelson, Surgeon T. H. Parke and A. J. Mounteney Jephson, led the advance guard out of camp on June 28, reaching Lake Albert five months later after a grueling march through dense forest. They did not contact Emin until April 1888 when Stanley found, to his astonishment, that the pasha was unwilling and unready to evacuate his province. Leaving him to assemble his troops, Stanley then returned to look for the missing rear column. He reached Balanya, just short of Yambuya, on Aug. 17, where he found the remains of the column, depleted and demoralized. Tippoo Tib had not sent the porters, Barttelot had been murdered and Jameson died soon after from fever.

Stanley blamed Barttelot and Jameson for the disaster, and on his return to England a controversy arose about the fate of the rear guard. This was the most bitter of the many quarrels that did so much damage to Stanley's reputation.

Back at the lake in Jan. 1889, Stanley heard that Emin and Jephson had been detained by disaffected troops, but eventually the party was reunited and on April 10, 1889, some 1,500 persons set out, arriving at Bagamoyo on the east coast on Dec. 4. Stanley cleared up some geographical points on this expedition. The mist-covered Ruwenzori range which had been concealed when Baker discovered Lake Albert in 1864, and which Stanley himself had passed unnoticed in 1876 was identified as the legendary Mountains of the Moon; the size of Lake Albert was correctly estimated and its tributary the Semliki river traced south to the lake which Stanley named Albert Edward on the homeward journey. In *Darkest Africa* (1890) is Stanley's account of this arduous and unlucky expedition.

**The Last Years.**—Stanley married Dorothy Tennant on July 12, 1890, and they adopted a son, Denzil. Stanley was naturalized a British subject in 1892, and sat in parliament as Liberal Unionist member for North Lambeth from 1895 to 1900. In 1897 he visited South Africa and wrote *Through South Africa* (1898). He was awarded a grand cross of the Bath in 1899. His

last years were spent mainly at Furze Hill near Pirbright, Surrey, a small estate bought in 1898.

Stanley died in London at 2, Richmond Terrace, Whitehall, on May 10, 1904, and was buried at Pirbright after a service in Westminster abbey.

**Summary.**—From a modern viewpoint, much contemporary criticism of Stanley appears unjust. To the select band of travelers whose centre was the Royal Geographical society, dedicated to the pursuit of knowledge, Stanley appeared as an outsider, an American journalist, with huge funds at his disposal. His motives in exploring were suspect and his methods were considered to be rough. His humble origin probably mattered less than he supposed to men who came, in fact, from a variety of social backgrounds, but his uncouth and uncooperative manners and his tendencies to self-righteousness and to boastfulness, ensured him an unpopularity which injures his reputation to this day. Harsh and humourless, touchy and intolerant, Stanley antagonized many who should have been his friends, and the controversies which arose around him have tended to obscure his achievements.

Nevertheless, to Stanley belongs the credit of having assembled the geographical discoveries and guesses of an earlier generation into the coherent whole which is the map of central Africa as it is now known. He is the bridge between the old and the new; at first the intrepid explorer, the friend of Livingstone and the discoverer of the Congo; then the pioneer who made the Congo Free State; finally, the elder statesman who lived into the age of Cecil Rhodes and of the opening up of modern Africa. See also references under "Stanley, Sir Henry Morton" in the Index.

**STANLEY, THOMAS** (1625–1678), English poet, translator and the first English historian of philosophy, was born at Cumberlow, Hertfordshire, in 1625, and educated by William Fairfax, son of the translator of Tasso. He became a good classical scholar and an enthusiastic student of French, Italian, and Spanish poetry. Stanley entered Pembroke Hall (later College), Cambridge, in 1639 and studied there and at Oxford, graduating M.A. in 1641. He traveled on the continent during the Civil War and on his return lived in the Middle Temple, London, where he devoted himself to literary work. He died in London on April 12, 1678.

Stanley was the friend of many poets and himself a prolific writer of original and translated verse. His first volume of poems appeared in 1647. Subsequent volumes included translations from Guarini, Marino, Petrarch, Ronsard, Ausonius, Oronta, Montalvan, and others. His classic renderings of the Anacreontic poems appeared in 1651, and the same collection contains his version of Pico della Mirandola's *Platonick Discourse upon Love*. His *History of Philosophy* was published in 1655–62 and his edition of Aeschylus with Latin translation and commentary in 1663. He had a graceful if tenuous gift as a lyrical poet and was a versatile and accomplished translator. His *History of Philosophy*, based largely on Diogenes Laërtius, long remained a standard work.

**STANLEY, WENDELL MEREDITH** (1904– ), U.S. biochemist and Nobel Prize winner, was born on Aug. 16, 1904, in Ridgeville, Ind. After receiving his Ph.D. degree from the University of Illinois, Urbana, in 1929, he became a research associate and instructor in chemistry there. In 1931 he entered the Rockefeller Institute for Medical Research, and in 1940 became a member of the institute. In 1948 he became director of the laboratory for virus research at the University of California. In research on the virus which caused the mosaic disease in tobacco plants, Stanley found that while it appeared to act like an inanimate chemical it presented evidence of being a living and growing organism. For "their preparation of enzymes and virus proteins in a pure form," Stanley and John H. Northrop divided equally one-half of the Nobel Prize in Chemistry in 1946, the other half being awarded to James B. Sumner for his discovery "that enzymes can be crystallized."

See E. Farber, *Nobel Prize Winners in Chemistry, 1901–1961* (1963).

**STANLEY**, an urban district of County Durham, Eng., lies 12 mi. NW of the city of Durham. Pop. (1961) 46,319. Since 1937 it has included the neighbouring urban districts of Annfield Plain and Tanfield, and the Craghead portion of the Lanchester rural district. Stanley is between 500 and 1,000 ft. (150 and 300 m.) above sea level, the highest point being Pontop Pike where stands the BBC television station for the northeast. From about A.D. 120 to 240 Stanley was the site of a Roman cattle camp for the supply of food to camps at Newcastle and South Shields. Causey Arch, built in 1727 as a wagon-way (tramroad) to a colliery, has a span of 103 ft. (31 m.). The first borings for coal to be made in England were at the now defunct White-le-Head colliery, early in the 18th century. Though principally a coal mining area other industries include the manufacture of roller bearings and clothing (including gloves), baking, and milk processing and distribution. (J. J. SH.)

**STANLEY** (PORT STANLEY), the chief town and, since 1844, capital of the Falkland Islands, lies on the northeast coast of East Falkland Island, along the southern slope of Port William inlet. The town's fine inner and outer harbours drew the early British settlers because of the protection afforded their sailing vessels. Though Stanley served as a naval base for British cruisers during World War II, the harbours now serve mostly merchant ships.

Stanley's population (1,074 in 1962) accounts for about half the population of the Falkland Islands. As a communications centre it has a radiotelegraphy station that maintains regular schedules with London, Oslo, Montevideo, and Buenos Aires, and a radio station maintained by the British Antarctic Survey for communications with British scientific bases in the Antarctic. The town is the headquarters of the British Antarctic Meteorological Service and the site of the islands' only hospital.

Notable structures include Christ Church Cathedral (1892), Government House, a monument commemorating the British victory over a German cruiser squadron in the battle of 1914, and the Town Hall. The last provides recreational facilities, a good library, and public offices, as well as a chamber for the Town Council. In the environs of Stanley are penguin rookeries and fine white beaches.

Stanley drew worldwide attention in 1966 as the site of an abortive "invasion" by a group of 18 Argentine nationalists who planned to capture the governor and with him the Falkland Islands. However, the governor was away, and, failing to persuade the townspeople that they had been captured, the invaders surrendered and submitted to the town's hospitality.

**STANLEYVILLE** (Congo): see KISANGANI.

**STANOVVOY RANGE** (STANOVVOY KHBEB), a mountainous range in the far east of the U.S.S.R., along the boundary between Amurskaya Oblast' and the Yakut Autonomous Soviet Socialist Republic. It is orientated west-east, linking the mountain complex of Transbaikalia (Zabaykal'ye) to the Dzhugdzhar Range which fronts the Sea of Okhotsk, and is part of the watershed between the Pacific and Arctic oceans, separating the Lena Basin to the north from the Amur Basin to the south. The mountains are generally not high, although reaching 8,268 ft. (2,520 m.) at the eastern end. They are densely forested with

taiga, dominated by larch, but higher summits are bare. The Aldan Highway, linking Yakutia (Yakutiya) to the Trans-Siberian Railway, crosses the range.

(R. A. F.)

**STANTON, EDWIN McMASTERS** (1814–1869), U.S. lawyer, secretary of war during the Civil War, was born on Dec. 19, 1814, in Steubenville, O. He entered Kenyon College, but lack of funds compelled him to leave before graduating. After studying law, he was admitted to the bar in 1836. A sharp, incisive reasoner, he soon became a successful attorney and handled important constitutional and civil law cases. In 1847 he moved to Pittsburgh, Pa., and in 1856 to Washington, D.C., where he achieved a wide practice in the federal courts. In 1851, in his most important case, he successfully argued before the U.S. Supreme Court that a bridge over the Ohio River at Wheeling, Va. (now West Virginia), which had been authorized by Virginia law, was an obstruction to interstate commerce. In 1858, as a special U.S. counsel opposing pre-Mexican War land grants alleged to have been made by the Mexican government in California, he won a series of notable victories. During these years he remained a Jacksonian Democrat.

THE GRANGER COLLECTION

EDWIN McMASTERS STANTON; PHOTOGRAPH BY MATHEW BRADY

In December 1860, when Pres. James Buchanan reorganized his cabinet, he appointed Stanton as attorney general; in this post Stanton opposed the abandonment of Ft. Sumter by the Union forces. Fearing the success of secessionist plotting, he secretly advised Republican leaders of the cabinet's proceedings. He became a caustic critic of the newly elected president, Abraham Lincoln, but nevertheless was made legal adviser to the secretary of war, Simon Cameron. When Cameron resigned under attack, Lincoln appointed Stanton as his successor on Jan. 13, 1862. During the remainder of the Civil War, Stanton proved to be an able, explosively energetic administrator. A nervous, asthmatic man, cranky and contradictory, he tirelessly presided over the giant Union military establishment. His sharp tongue and brusque manner provoked violent quarrels with nearly every important Union military commander. In the confusion following Lincoln's assassination, Stanton, for a few days, was a virtual dictator.

Remaining in the cabinet after Lincoln's successor, Andrew Johnson, became president, Stanton was soon at loggerheads with him over reconstruction policy. Stanton used his position to further harsher reconstruction measures than Johnson desired, and so forced Johnson to attempt his removal. Stanton refused to be dismissed, claiming that the Tenure of Office Act, passed over Johnson's veto, protected him in his official position. Because Johnson persisted, he was impeached by the House of Representatives. When the Senate refused to convict Johnson, Stanton surrendered his office on May 26, 1868, and returned to the practice of law. He died in Washington, D.C., on Dec. 24, 1869, four days after the Senate had confirmed his appointment to the U.S. Supreme Court.

See Fletcher Pratt, *Stanton, Lincoln's Secretary of War* (1953); B. P. Thomas and H. M. Hyman, *Stanton: the Life and Times of Lincoln's Secretary of War* (1962).

(R. J. Ro.)

**STANTON, ELIZABETH CADY** (1815–1902), U.S. leader in the women's rights movement, was born in Johnstown, N.Y., on Nov. 12, 1815. The daughter of Judge Daniel Cady, she learned in his law office of the discriminatory laws under which women lived, and observed many tragic cases which determined her to win equal rights for her sex. In 1840 she married the abolitionist Henry Brewster Stanton. In 1848 she circulated petitions to secure the passage in New York of a law giving married women property rights. Also in 1848 she and Mrs. Lucretia Mott (*q.v.*) were the leaders of the first women's rights convention in the U.S.

at Seneca Falls, N.Y. For it Mrs. Stanton drew up a woman's bill of rights setting forth the inferior and unjust position of women in state, church, law, and society, and resolutions demanding redress of wrongs, which were adopted. A resolution, introduced without Mrs. Mott's approval, favouring women's suffrage (*q.v.*) was the first organized demand for it in the U.S. In 1850 Mrs. Stanton became associated with Susan B. Anthony (*q.v.*), and for 40 years they worked together, Mrs. Stanton writing and Miss Anthony managing business affairs. They cooperated in editing *The Revolution* (1868–70), a women's rights newspaper, and with Matilda Gage were joint editors of the first three volumes of *The History of Woman Suffrage* (six volumes, 1881–1922). Mrs. Stanton died in New York City on Oct. 26, 1902.

See T. Stanton and H. S. Blatch (eds.), *Elizabeth Cady Stanton as Revealed in Her Letters, Diary and Reminiscences*, 2 vol. (1922); Alma Lutz, *Created Equal* (1940).

**STANYHURST, RICHARD** (1547–1618), English translator of Virgil, was born in Dublin. At University College, Oxford, his commentaries on Porphyry won him a reputation for precocious learning. He read for the bar and after a stay in Ireland became a Roman Catholic. Most of his subsequent life was spent in the Netherlands, where he became a priest (probably *c.* 1607) and a chaplain to Archduke Albert of Austria. He died in Brussels.

Stanyhurst wrote the *Description and History of Ireland* found in Holinshed's *Chronicles* (1577) and Latin works including *De rebus in Hibernia gestis* (1584). His chief work, however, was his translation of *The First Four Books of Virgil His Aeneis* (1586), which attempted to prove Gabriel Harvey's theory that classical prosody could be applied to English poetry.

Thomas Nashe said that his translation "trode a foule, lumbring, boystrouy, wallowing measure." But though forced to the point of absurdity and unintelligibility, from a prosodic viewpoint his translation, with its attempt to indicate quantity by spelling, is interesting.

See editions of the *Aeneis* by E. Arber (1880) and D. van der Haar (1933).

**STAR**, a self-luminous object, shining by radiation derived from energy sources within itself. By contrast, planets shine by reflected light only, while gaseous and diffuse nebulae may shine either by reflected light or (essentially) by fluorescence. The universe contains billions of stars, only about 6,000 of which are visible to the naked eye. As noted below, stars are not identical to one another but vary considerably in many respects, such as brightness, colour, age, size, temperature, and chemical composition.

As far as its properties can be compared with those of other stars, the sun is a typical star. It has a mass more than 300,000 times that of the earth,  $1.99 \times 10^{30}$  kg., a radius of 696,000 km. (about 432,200 mi.) and a power output of  $3.8 \times 10^{23}$  kw. The masses, radii and luminosities of other stars are often expressed in terms of that of the sun.

Table I gives data pertaining to the 20 brightest stars or, more precisely, stellar systems, since some of them are double or even triple stars. Note that all of these stars are as bright or brighter than the sun; some of the companions are fainter. Stars such as Altair,  $\alpha$  Centauri and Procyon are called dwarf stars; their dimensions are roughly comparable with that of the sun. Sirius and Vega are also dwarf stars; their higher temperatures give a large rate of emission per unit area. Aldebaran, Arcturus and Capella are examples of giant stars. Thus, measurements with the interferometer (which gives the angular diameter) combined with parallax measurements give diameters of 24 and 45 solar diameters for Arcturus and Aldebaran, respectively. Betelgeuse and Antares are examples of supergiants. The latter has a diameter 200 times that of the sun whereas the diameter of Betelgeuse (if we choose a distance 1,500 light-years) is 220 times. Other examples of supergiants include  $\alpha$  Herculis and the variable Mira whose diameters are 580 and 460 times as great as that of the sun. Several white dwarf stars of low luminosity and high densities are listed.

Table II gives the 20 nearest known stars. Only  $\alpha$  Centauri, Procyon and Sirius appear in both lists. All other stars are fainter

than the sun and most of them can be seen only by the use of a telescope. The highly luminous stars can be seen at great distances; intrinsically faint stars can be seen only if they are very near the sun.

This article is divided into the following sections and subsections:

## I. DISTANCES OF THE STARS

Before any adequate discussions of stars as celestial bodies can be made, it is necessary to know their distances. Several methods have been devised, some of them of a statistical nature, which permit the distances of various types of objects to be ascertained.

**1. Trigonometric Parallaxes.**—If the position of a nearby star is measured from two points on opposite sides of the earth's orbit, a small angular displacement will be observed. Using the earth's orbit as the base line, the distance of the star can be found from the angular size of the parallax,  $p$  (see fig. 1). If  $p = 1''$ , the star's distance would be 206,265 times the distance of the earth from the sun, or 3.26 light-years. This unit of distance is called the parsec; hence

$$r = 1/p \quad (r \text{ in parsecs if } p \text{ is in seconds of arc}) \quad (1)$$

The nearest star (the triple-star system of  $\alpha$  Centauri) has a

FIG. 1.—PARALLAX OF A STAR  
Circle AB represents orbit of earth; angle CSA is heliocentric parallax,  $p$

parallax of  $0''.752$ . Its distance is 1.33 parsecs, or 4.34 light-years. Trigonometric parallaxes can be measured only for relatively close stars. The probable error of such a parallax is  $0''.005$ . This means that there is a 50-50 chance that a star whose parallax is  $0''.01$  lies between 67 and 200 parsecs (corresponding to  $p = 0.015$  and  $0.005$ , respectively) and an equal chance that it lies outside that range.

For measuring the distance of more remote stars other methods must be used.

## 2. Statistical Methods Based on Stellar Motions.

In spite of their designation as "fixed stars," the stars are neither fixed in positions on the celestial sphere, nor in space. Edmund Halley, from a comparison of the positions of Arcturus, Aldebaran and Sirius, in the 18th century with earlier measurements showed that there was an actual motion of the stars across the line of sight (proper motion). The amount of the proper motion (in seconds of arc per year) depends on two factors, the distance of the star and its velocity in km. per second in the plane of the celestial sphere (tangential velocity)

$$T = 4.74 \frac{\mu \text{ sec.}}{\text{parallax}} \quad (2)$$

or tangential velocity =  $\frac{\text{annual proper motion}}{\text{parallax}} \times 4.74 \text{ km. per second.}$

The motion in the line of sight (radial velocity) is obtained directly from spectroscopic observations (fig. 2). If  $\lambda$  is the wave length of a characteristic spectrum line emitted by the star (e.g., a line of iron) and  $\lambda_L$  is the wave length of the same line measured in a laboratory on the earth, the difference  $\Delta\lambda = \lambda - \lambda_L$  is related to the radial velocity  $V$ , by Doppler's principle (see LIGHT: Waves and Interference) by

$$\Delta\lambda/\lambda = V/c \quad (3)$$

where  $c$  is the velocity of light. Shifts of the spectral line (positive  $V$ ) toward red indicate recession. If the parallax is known, measurements of  $\mu$  sec. and  $V$  enable one to determine the space motion of the star. Radial velocities must be corrected for the motion of the earth around the sun so that they will refer to the relative line-of-sight motion of the star with respect to the sun.

The observed motion of a given star is made up of two effects, the motion of the star with respect to the average of the nearby stars (the local standard of rest) and the motion of the sun with respect to this same standard of rest. The first problem that has to be solved is the determination of the sun's motion with respect to the nearby stars, both in velocity and direction. This vector

quantity is established most reliably from radial velocity data. Stars in the region of the sky toward which the sun is moving (apex of the sun's way) show a predominantly negative velocity (approach) whereas those in the opposite region of the sky show a positive velocity (recession). Stars at position  $90^\circ$  away from the apex or antapex show a random mixture of positive and negative radial velocities. A statistical analysis of the observed radial velocities permits the determination of the apex and the velocity of the sun  $V_\odot$  with respect to the average of the nearby stars. From the radial velocities of 2,149 bright stars, W. W. Campbell and J. H. Moore found the position of the apex to be  $\alpha = +271^\circ$ ,  $\delta = 29^\circ$  (constellation

\* (w.d.) = white dwarf.

†  $\alpha$  Centauri has a distant companion, Proxima Centauri, an 11th magnitude M star.

‡ Peter van de Kamp lists two additional components to Capella: an M1 star,  $M_V = 10.0$ , and an M5 star  $M_V = 13.7$  with luminosities

0.014 and 0.0005 that of the sun (*Publications of Astronomical Society of the Pacific*, 65:30, 1953).

§ It is assumed that Rigel and Betelgeuse both belong to the great Orion complex, 1,500 light-years distant.

The data are quoted largely from G. W. Allen, *Astrophysical Quantities*, and from P. van de Kamp (*op. cit.*).

of Hercules not far from star  $\mu$  Herculis). The space velocity of the sun was found to be 19.5 km. per second.

Once the direction of the solar motion is known, the proper motion of any star can be divided into two components, one along the great circle passing through the apex, the star, and the antapex and the other perpendicular thereto. The first mentioned component is called the *upsilon* component, the other is called the *tau* component (fig. 3). Now the *upsilon* component contains the effects of both the star's own peculiar motion and the reflection of the sun's motion. The backward drift caused by the sun's motion will be a maximum for stars  $90^\circ$  from the apex, and zero at both the apex and antapex. The *tau* component is unaffected by the solar motion. Let us suppose that  $|\bar{V}_s|$  is the average radial velocity (without regard to sign and corrected for the solar radial velocity) of all the stars of a particular kind; e.g., giant stars like Arcturus. Now  $|\bar{V}_s| = |\bar{V}_\tau|$ , the average *tau* component of velocity, if the stellar motions are at random. Hence, using equation (2)

$$\bar{p} = 4.74 \frac{|\bar{V}_\tau|}{|\bar{V}_s|} \quad (4)$$

where  $(\bar{V}_\tau)$  is the average of *tau* components without regard to sign. Notice that what is obtained is the average parallax; the parallax cannot be obtained for any individual star, since in any particular instance  $V_s$  will not be the same as  $V_\tau$ . Nevertheless, if attention is confined to groups of stars of the same intrinsic luminosities (and not over too great a spread in distance) the method will give good results.

It is assumed that the stars are moving at random and, strictly speaking, solar motion should be determined with respect to this particular group of stars. Statistical parallaxes fail for very remote objects and require reliable proper motions. Since the accuracy of a proper motion depends on the time interval between two epochs of observation, an increasing base line in time will serve to improve the data.

**3. Moving Cluster Methods.**—If a group of stars constitute what is called a moving cluster, their space motions are parallel to one another. Provided the cluster fills a substantial area of the sky, the place in the celestial sphere toward which the cluster appears to be moving, i.e., its convergent point, can be found from a careful observation of the proper motions (see fig. 4). The radial velocities are also measured. The angular distance  $\theta$  between the centre of the cluster and its convergent point being known, the tangential velocity  $T$  can be computed in km. per second from the radial velocity  $V$ . Since the tangential velocity expressed in seconds of arc is the total proper motion  $\mu$  sec., the parallax can be found from equation (2). This method has been applied to the Ursa Major cluster (which includes five of the seven stars of the Big Dipper) and to other groups such as the Hyades.

**4. Dynamical Parallaxes.**—The distance of a double star whose orbit is known can be found from its apparent brightness provided the star follows the mass-luminosity correlation (see below). This method is useful for double stars in clusters (such as the Pleiades).

**5. Membership in Galactic Clusters.**—A star cluster such as the Pleiades contains stars similar in intrinsic brightnesses and colours to the sun and its neighbours. Hence if the apparent brightnesses of these stars are measured and compared with their

FIG. 3.—PERSPECTIVE DIAGRAM SEEN FROM ABOVE OF EFFECTS OF SOLAR MOTION

P is apex, X is antapex, A is position of a star where proper motion is observed. AE (perpendicular to lines AC and AB) is *tau* component of star's motion; it lies perpendicular to plane of great circle, PAX, passing through apex, star and antapex. AC is *upsilon* component; AB, the reflection of the sun's motion  $V_s$ . Vectors BD and CB represent motion of star with respect to local standard of rest

true brightnesses, the distance of the cluster can be found from an application of the inverse-square law. If absorption of light in interstellar space between the cluster and the sun occurs, its amount has to be determined and the apparent brightnesses of the stars corrected to what they would have been for no interstellar absorption. This method is standard for establishing the distances of remote clusters.

**6. Galactic Rotation.**—The Milky Way is in slow rotation about a centre roughly 28,000 light-years distant from the sun. This rotation is like that of the planetary system in that the stars more distant from the centre travel more slowly. The general nature of the galactic rotation can be established from the gaseous component of the interstellar medium with the aid of both optical and radio-frequency observations. From the radial velocities of very remote stars their distances may be obtained with the aid of equations derived by J. H. Oort.

**7. Remote Systems.**—All of these methods fail for remote systems such as the Magellanic clouds or the Triangulum or Andromeda galaxies. For these systems other methods must be used. Certain types of objects, such as blue stars, supergiants and variable stars, are recognized in some of them. The intrinsic brightnesses of these objects being known, their apparent brightnesses in the stellar systems under investigation are measured and thus their distances are obtained. Again, corrections for space absorption must be applied if necessary.

Checks on the methods of distance determinations can sometimes be made when two or more different techniques can be applied to the same stars or system of stars. One example is provided by the Ursa Major moving cluster where R. M. Petrie and B. Moys obtained distances in good agreement with those found from direct trigonometric parallaxes of the same stars. A second illustration is supplied by the binary Procyon. The orbit of the bright star about the centre of gravity of the system and its inclination to the plane of the sky are known. K. Strand measured the radial velocity of the star from plates secured at Mount Wilson and converted them to actual orbital velocities. With the aid of the known period, he then found the average radius (semi-major axis) of the orbit,  $a$ . Since  $a$  is also known in seconds of arc, the parallax is found directly. Again, results in good agreement with the trigonometric measurements are found. Occasionally discrepancies are found, as in the Pleiades, but such discordances sometimes turn out to yield other dividends, such as clues to stellar evolution.

To summarize, stellar distances are accurately known for nearby objects. Stars in remoter parts of the galactic systems do not yield such satisfactory values for their distances.

Finally, it should be mentioned that the distance, or more accurately speaking the intrinsic brightness of a star whose apparent brightness can be readily measured, can sometimes be found from its spectrum. Such spectroscopic parallaxes are becoming increasingly important in astronomy, but they have to be calibrated by measuring the distances of the prototype of each spectroscopic species of stars by some method such as those described in the preceding sections.

## II. OBSERVABLE DATA FOR STARS

**1. Nomenclature.**—The earliest designations of the stars still in common use are the Arabic names. These follow no particular system, are often fanciful in character and are rarely used except by navigators and amateurs. The brighter stars in each constellation are now denoted by a system introduced in 1603 by Johann Bayer. The brightest star in the constellation is denoted as  $\alpha$ , the next brightest as  $\beta$ , etc. When stars are of comparable brightness, as in the Big Dipper, they are lettered according to their position in the constellation. Later John Flamsteed introduced a system of numbers assigned in order of right ascension.

Stars too faint to be given a Bayer letter or Flamsteed number are listed in star catalogues, the most extensive of which is the *Bonner Durchmusterung* (B.D.). The first B.D. catalogue prepared by Argelander gives the positions and rough brightnesses of more than 324,000 stars north of  $-2^\circ$  declination. Schönfeld extended the catalogue to  $23^\circ$  south and added 133,000 stars while

‡The faint component has a planetlike companion.

Compiled from C. W. Allen, *Astrophysical Quantities*, and Peter van de Kamp, *Publications of Astronomical Society of the Pacific*.

the rest of the southern hemisphere was covered by the *Cordoba Durchmusterung* (C.D.) and the *Cape Photographic Durchmusterung* (C.P.D.). Star charts are provided for each catalogue so that the identification of a given star is not difficult.

A somewhat less extensive catalogue but one that gives accurate positions for 33,342 stars is the *Boss General Catalogue*. The stars are listed according to their positions for 1950. A much smaller catalogue, the *Fourth Fundamental Catalogue* (1963), gives accurate positions for 1,538 stars. It is generally accepted as the basic standard reference for astrometric work. Perhaps the most frequently used catalogue is the *Henry Draper Catalogue* (H.D.), which gives the brightnesses, spectral classes and rough positions for 1900 for 225,000 stars (*Harvard Observatory Annals*, vol. 91–99). Extensions have been published for certain regions in the sky. The roughly 6,000 naked-eye stars plus many telescopic stars are included in the H.D. catalogue.

For yet fainter stars, e.g., objects 100 times as faint as the dimmest star that can be seen with the unaided eye, the *Astrographic Catalogue* or *Carte du Ciel* can be used; however, it is not yet complete for all parts of the sky.

Star charts or photographs of large regions of the sky have also been published. The most extensive series of these charts is the National Geographic society–Palomar survey carried out with the 48-in. Schmidt camera. This survey covers only the part of the sky observable from Palomar mountain but includes photographs taken in both the blue spectral region and the red spectral region with an appropriate filter. Hence, strongly coloured stars and gaseous nebulae can be readily identified. More within resources of amateurs are the B.D. charts or the Skalnate Pleso charts.

**2. Stellar Positions.**—Accurate measurements of stellar position play a basic role in many problems of modern astronomy. The positions of the brighter stars in the equatorial co-ordinate system (right ascension  $\alpha$  and declination  $\delta$  for some given epoch) are measured with a meridian circle. The fainter stars are measured upon photographic plates with respect to these brighter stars and finally the entire group is referred to the system of extragalactic nebulae. The reason for this last step is that these external galaxies define an essentially fixed or immovable system, whereas both the bright and faint stars are affected by large-scale stellar motion connected with galactic rotation.

For problems concerned with the structure of the galaxy, the positions are often given in terms of galactic co-ordinates, galactic longitude,  $l$ , and galactic latitude,  $b$ , in which the plane of the Milky Way is the analogue of the plane of the equator.

**3. Stellar Motions.**—From accurate measurements of stellar

positions one can obtain the proper motions whose fundamental role in the determination of stellar distances has already been indicated. Special efforts have been made to detect stars of large proper motion since these tend to be nearby, often intrinsically very faint stars. Parallax programs are often based on lists of stars of large proper motion. Although proper motions can be measured for very faint stars, radial velocities can be determined only for stars whose spectra can be photographed. This limits our measurements to fairly bright stars. (See SPECTROHELIOGRAPH.)

**4. Brightness of the Stars.**—The brightnesses of the stars are usually expressed by means of their magnitudes, a usage which has come down from classical antiquity. A star of the 1st magnitude is 2.5 times as bright as one of the 2nd magnitude, which in turn is 2.5 times as bright as one of the 3rd magnitude, etc. A star of the 1st magnitude is 100 times as bright as one of the 6th magnitude. Sirius, apparently the brightest star in the sky, is  $-1.5$ ; Canopus, the second brightest, is  $-0.7$ , while the faintest star that can normally be seen without telescopic aid is of the 6th magnitude. Stars as faint as the 23rd magnitude have been measured with the Hale 200-in. telescope.

The scale of magnitudes constitutes a geometrical progression. To convert from magnitudes to light ratios the formula

$$\log \frac{I_n}{I_m} = 0.4 (n - m) \quad (5)$$

is used where  $I_n$  and  $I_m$  are the brightnesses of stars of magnitudes  $n$  and  $m$ , respectively. To the extent that brightness ratios can be regarded as power ratios we can think of one magnitude as corresponding to four decibels. Note that magnitudes are actually defined in terms of observed brightnesses and this quantity will depend on the light detecting device employed. Thus we may speak of visual magnitudes as measured with the eye, photographic magnitudes as measured with a photographic plate, and also of various types of photoelectric magnitudes.

In such a way one defines the magnitude scale; one must also give the zero point of the scale. This point is fixed arbitrarily with regard to the star catalogues of Ptolemy and Hipparchus.

The brightnesses which are actually measured give the apparent magnitudes. These cannot be converted to intrinsic brightnesses until the distances of the objects concerned are known. The absolute magnitude of a star is defined as the magnitude it would have if it were placed at the standard distance of 10 parsecs, or 32.6 light-years (2,062,650 astronomical units). The apparent visual magnitude of the sun is  $-26.9$ , that of the full moon  $-12.7$  and the brightest star is  $-1.5$ . The absolute magnitude of the sun corresponds to a diminution in brightness by a factor  $(2,062,650)^2$  and is therefore  $-26.9 + 2.5 \times \log (2,062,650)^2 = -26.9 + 31.6 = 4.7$ . The corresponding absolute magnitude of the full moon would be about  $+32$  and would require a telescope with an aperture of about a quarter-mile. The brightest stars such as Rigel ( $\beta$  Orionis) have absolute magnitudes of  $-8$  or even  $-9$ . (See Table I.) The faintest known star, the companion to B.D. + 4° 4048, which was discovered by G. van Biesbroeck, has an absolute visual magnitude 18.1 which makes it 200,000 times fainter than the sun. A number of such stars may exist in space, but they are extremely difficult to detect. Included among the faint stars are the white dwarflike objects that are extremely dense stars near the end of their evolution.

**5. Stellar Colours.**—Even the casual observer knows that all stars are not of the same colour. Consider the constellation of Orion, for example. Most of the naked-eye stars are blue-white in colour, but Betelgeuse ( $\alpha$  Orionis) is a deep red. As seen in the telescope, Albireo ( $\beta$  Cygni) consists of two stars: one blue, the other orange. Some quantitative means of measuring stellar colours is needed. One method is to compare the visual magnitude of the star with a magnitude measured with a photographic plate. The photographic plate is insensitive to yellow and red light but sensitive to blue and violet, so that hot blue stars appear bright, and yellow and red stars are faint. The scale of photographic and all other magnitudes is the same as for visual magnitudes, i.e., one magnitude step corresponds to a brightness ratio of 2.5 but the zero point is adjusted so that white stars with surface temperatures

of about 10,000° K. have the same visual and photographic magnitudes. A blue star with a temperature of 20,000° K. is then brighter photographically than visually by about half of a magnitude, whereas a cooler star like the sun ( $T = 5,700^\circ \text{K.}$ ) is about half a magnitude fainter photographically than visually. The conventional colour index is defined as the photographic magnitude minus the visual magnitude. According to this system, the colour index of the sun is  $M_p(\odot) - M_v(\odot) = +5.26 - 4.73 = 0.53$ .

Later, "visual" magnitudes were determined photographically with the aid of orthochromatic or yellow-sensitive plates and yellow filters. Such magnitudes are referred to as photovisual magnitudes and differ from visual magnitudes less than visual magnitudes (as found by different observers) differ among themselves.

As a fundamental light or colour measuring device, the photographic plate has certain disadvantages. In particular, the amount of blackening of the emulsion is not proportional to the intensity of the light (or to the exposure time). The connection between blackening and intensity can be calibrated but it varies with the colour of the light, development and exposure time. Fundamental measurements of stellar magnitudes and colours are now made by photoelectric photometry although the photographic plate continues to play a vital role as an interpolation device. For example, it may be necessary to measure the magnitudes and colours of hundreds of stars in a star cluster. Such a task would be prohibitive if one had to observe each individual star with a photoelectric photometer. Instead, the observer selects a sequence of 20 or 30 stars covering the entire range of magnitude and colour in the cluster, measures them carefully with the photoelectric photometer and compares with them all the other cluster stars recorded on the photographs. (See PHOTOMETRY, CELESTIAL: *Photoelectric Photometry*; PHOTOGRAPHY, CELESTIAL.)

The photoelectric photometer has several great advantages. First, it permits measurements to be made with an accuracy limited only by the atmosphere. Second, the relation between the number of electrons ejected from the photocathode and the light intensity is a strictly linear one. Stellar colours can be measured very quickly and conveniently by placing appropriate filters in front of the cell.

The older system of stellar magnitudes employed only photographic and photovisual (or visual) magnitudes. It encountered a number of severe difficulties. Only two of them will be mentioned here. The first grows out of the fact that most stars do not radiate like black bodies. In particular, stars with temperatures in the range 8,000° K. to 20,000° K. have a very strong drop in their energy outputs near  $\lambda 3,700 \text{ \AA}$  and continuing to the ultraviolet. When the magnitudes of these stars were determined with photographic lenses, this region was cut out by the flint glass components of the achromatic objectives. But when the same stars were observed with reflecting telescopes with aluminized mirrors, radiation from the ultraviolet region was included, with the result that photographic magnitudes highly discordant with respect to previous determinations were obtained. A second difficulty is that when only one colour is observed ( $M_p - M_v$ ), it is impossible to distinguish between the effects of reddening due to space absorption and reddening due to a low temperature. That is, if a star is measured and its colour is found to be red, it is not possible to say whether the star is red because it is cool or whether it is really a hot star whose colour has been reddened by the absorption and reddening of light in space. By measuring the magnitudes of the same stars in three colours it is possible to overcome these difficulties. W. Becker used the methods of photographic photometry to establish the amount of interstellar reddening.

J. Stebbins and A. E. Whitford used a photoelectric photometer with colour filters to measure six colours extending from the infrared to the limit of transmission of the earth's atmosphere. In many respects the most satisfactory and probably the most widely used and practical system of stellar magnitudes and colours, however, is the UBV photoelectric system of Harold Johnson and W. W. Morgan. The ultraviolet or "U" filter has a broad band pass centred near  $0.35 \mu$  ( $3,500 \text{ \AA}$ ). It transmits the region of

the spectrum beyond the big intensity drop at  $\lambda 3,700$  in the moderately hot stars. The blue or "B" filter has a broad maximum centred near  $\lambda 4,200$  with cutoffs in both the ultraviolet and green. It renders magnitudes roughly similar to (but not identical with) the old system of photographic magnitude. The visual or "V" filter transmits over a broad band pass from about  $0.49 \mu$  to  $0.65 \mu$  with a maximum near  $0.55 \mu$ . It yields essentially visual magnitudes. The Johnson-Morgan system of colours and magnitudes is precisely defined in terms of stars of accurately known spectral classes and intrinsic luminosities; i.e., surface temperatures and surface gravities. Furthermore, the stars cover a sufficiently wide range in colour, absolute magnitude and distribution over the sky to permit the observer to use them most effectively. In this system, the visual absolute magnitude of the sun is  $M_v = 4.79$ , and its corresponding blue magnitude is  $M_B = +5.41$ ; the colour index,  $B - V$ , is  $+0.62$ .

**6. Stellar Spectra.**—Probably the largest amount of information that is attainable for a single star is obtained from its spectrum. The spectrum of a star gives at once its temperature and information about its chemical composition. Stellar spectrograms secured with a slit spectrograph on a sufficient scale reveal also whether the star is a member of a close binary system, whether it is a highly luminous supergiant, a moderately bright giant or a dwarf star like the sun.

Such spectrograms may permit a determination of the quantitative chemical composition of the star. They will also tell if the star is in rapid rotation, if it has an extended atmosphere and if it has a strong magnetic field.

(See SPECTROSCOPY, ASTRONOMICAL.)

The vast multitude of stars fall in a small number of spectral classes. The system of spectral classification embodied in the *Henry Draper Catalogue* embraces the following classes (ranging from the hottest to the coolest stars): O B A F G K M. (See fig. 5.) This group is supplemented by the R and N stars (sometimes referred to as the carbon C stars) and the S stars. The R, N and S stars differ from the others in chemical composition; they are invariably giant or supergiant stars and include no dwarfs.

The spectral sequence, O-M, represents a group of stars of essentially the same chemical composition but of differing temperatures and atmospheric pressures. This simple interpretation was put forward in the early 1920s by Meg Nad Saha and has provided the basis for all subsequent interpretations of stellar spectra. The spectral sequence is also a colour sequence; the O and B stars are intrinsically the bluest and hottest; the M, R, N and S stars are the reddest and coolest. When the effects of space reddening are eliminated and stars of a given kind, e.g., dwarf stars, are considered, there is a one-to-one correspondence between colour and spectral class.

Consider first the cool stars of class M. They exhibit spectral lines of familiar metals such as iron, calcium, magnesium, etc., and also (particularly in the red and green part of the spectrum) strong bands with sharp edges on the red side caused by titanium

FIG. 5.—REPRESENTATIVE SPECTRAL TYPES

Principal Draper classes are represented. Note the great strength of the hydrogen lines in spectral class A1 (Sirius), the helium lines in BO ( $\epsilon$  Orionis), the metallic lines in G0 (Capella) and K2 (Arcturus) and the molecular bands in the long period variable, M6 (Mira)

oxide. In the cooler stars of class M these bands become very strong and smother the continuous spectrum of the star. In spectral class K, represented in fig. 5 by Arcturus, the titanium oxide (TiO) bands disappear, and the spectrum exhibits a wealth of lines of the metals. A few especially refractory fragments of molecules such as cyanogen (CN), the hydroxyl radical (OH) and CH persist in these stars and even in G stars such as the sun. The spectra of the G stars are dominated by the metallic lines, particularly those of iron, calcium, sodium, magnesium and titanium. The  $\lambda 4,227$  line of calcium (produced in the flame or bunsen burner) is much weaker than in the M stars, but the  $\lambda 3,968$  and  $\lambda 3,933$  (H and K) lines of ionized calcium ( $\text{Ca}^+$ ) are much stronger than any other feature. This behaviour of calcium illustrates the phenomenon of thermal ionization. At low temperatures a calcium atom retains all its electrons and radiates a spectrum characteristic of the neutral or normal atom. If the temperature is raised, collisions between atoms and electrons and the absorption of radiation tend to detach electrons and produce ionized  $\text{Ca}^+$  atoms. At the same time ions and electrons may recombine to produce neutral calcium atoms. The situation may be expressed by the reversible reaction:

If the temperature is high or the electron pressure low, or both, the atoms tend to be mostly ionized. At low temperatures and high densities the equilibrium favours the neutral state. The concentrations of ions and neutral atoms can be computed from the temperature, density and the ionization potential (the energy required to detach an electron from the atom; it is usually expressed in electron volts). In the stars of spectral class F, the lines of the neutral atoms become relatively weak in comparison with those of the ionized atoms. The hydrogen lines become stronger, attaining their maximum intensities in spectral class A, where the temperature is around  $9,000^\circ \text{K}$ . Thereafter they gradually fade as hydrogen becomes ionized.

Spectral lines are produced by transitions between energy levels. The yellow D lines of sodium or the H and K lines of ionized calcium are produced by jumps from the lowest energy levels of these atoms. The observable hydrogen lines, however, are produced by jumps from atoms in the second energy level, which lies far above the ground level. Only at high temperatures are sufficient numbers of atoms maintained in this level by collisions, radiations, etc., to permit an appreciable number of absorptions to occur. At the low temperatures of the M or even of the K stars there are few atoms in the second level. On the other hand, at the very high temperatures of the B and O stars, the hydrogen atoms are mostly ionized and thus cannot absorb any radiation.

Another feature to be noticed is that the lines of most ionized metals, such as iron, in the F stars never attain the strength that their neutral lines do in the K stars. This effect is partly due to the circumstance that these lines involve higher energy levels which are more sparsely populated than the lower levels. Another factor, however, is that the general fogginess or opacity of the atmospheres of these hotter stars becomes greatly increased. For example, above each square inch of the visible surface of the sun there is about 20 times as much material as there is above each square inch of the surface of Sirius, an A1 star.

The continuous (as distinct from the discrete or line) spectrum of the sun is produced primarily by the photodissociation of the negative hydrogen ion. In the solar atmosphere a small number of hydrogen atoms pick up extra electrons to form negative ions. When these are subsequently destroyed by photodissociation they produce a continuous absorption of radiation. In the hotter stars the principal source of absorption is the photoelectric effect on hydrogen atoms.

Photoelectric absorption by normal hydrogen atoms is confined to the remote ultraviolet, but if the hydrogen atoms can become excited to their second or third energy levels, the photoionization energies then required are much lower and the continuous absorptions fall in the normally observable range. Other sources of opacity exist but are relatively minor except in the coolest stars with dense band absorption.

The hotter stars of spectral class B, e.g.,  $\epsilon$  Orionis, are characterized by lines of helium, singly ionized oxygen, nitrogen and neon. In the O stars, the lines of ionized helium appear. Other prominent lines include those of doubly ionized nitrogen, oxygen and carbon and trebly ionized silicon. In the hottest stars of spectral class O, the lines of hydrogen and helium are still visible.

The physical processes behind the formation of stellar spectra are well enough understood to permit determinations of temperatures, densities and quantitative chemical compositions of stellar atmospheres. The star studied in greatest detail is, of course, the sun, but other stars also have been investigated carefully.

Although the general line intensity variations of the spectral sequence can be understood in terms of a variation of temperature, these same features also depend on the densities of stellar atmospheric gases. These densities depend in turn on the surface gravities. Stars of high surface gravities (dwarfs) tend to have high densities; those of low surface gravities, giants and supergiants, have relatively low surface densities. The hydrogen lines provide an illustration in point. Normally, an undisturbed atom radiates a very narrow line. If its energy levels are disturbed by charged particles passing nearby it will no longer radiate at its characteristic frequency  $\nu_0$  but at some nearby frequency  $\nu_1 = \nu_0 + \Delta\nu_0$ . In a hot gas, charged particles will pass radiating atoms in a random fashion and at different distances, for each of which there is a corresponding value of the frequency shift  $\Delta\nu$ . The spectrum line radiated by the whole mass of gas accordingly will be blurred out, the amount of the blurring depending on the density of the gas in a known fashion. The dwarf stars of spectral class A such as Sirius show broad hydrogen lines with extensive "wings" whereas supergiant A stars such as Deneb ( $\alpha$  Cygni) show relatively narrow hydrogen lines. Another example is the  $\lambda 4,227$  line of neutral calcium, which shows broad wings in dwarf M stars and is very narrow in supergiants. The ionization of the calcium in the supergiant is greater than in the dwarf, but the principal effect arises from density broadening. Luminosity effects in stellar spectra have to be established empirically. The procedure is (1) to observe a group of stars of different but known absolute luminosities; (2) to select among these stars spectral lines that are sensitive to luminosity but are not used for assigning the Draper class. Molecular bands (such as those of CN) as well as atomic lines are used for absolute magnitude criteria. Much effort has been expended on this problem by E. Hertzsprung, W. S. Adams and A. Kohlschütter, A. H. Joy, B. Lindblad and his associates in Sweden, and many others. In the modern system of spectral classification introduced by W. W. Morgan and P. C. Keenan, the luminosity class of the star is assigned along with the Draper class. Thus  $\alpha$  Persei is classed as F5Ia, which means that it falls about halfway between the beginning of class F (FO) and of class G (GO). The Ia means that it is a particularly luminous supergiant with an absolute visual magnitude of the order of  $-7$ . The star  $\pi$  Cephei G2III is a giant falling between GO and KO but much closer to GO. The sun is classified as G2V. A star of luminosity class II falls between supergiants and giants; one of class IV is a subgiant. (See Table I.)

Positions, magnitudes and colours can be measured for vast numbers of stars. Spectrograms can be secured for certain of the brighter stars. If the star is close enough, its trigonometric parallax can be measured. If it is a member of a visual binary system whose orbit and parallax are known, the mass can be found. The orbit of each component must be known with respect to the centre of gravity in order to determine the individual masses. The masses of components of eclipsing binaries can also be found if both spectroscopic and photometric data are available.

**7. Stellar Diameters.**—Eclipsing binary systems provide the most extensive data on stellar dimensions. Fortunately, eclipsing systems include examples not only of dwarf stars such as the sun and Sirius but also of supergiant stars such as 31 Cygni and VV Cephei. The angular diameters of bright red giant and supergiant stars were measured in the 1920s with the Michelson stellar interferometer. The principle upon which this instrument is based goes back to the interference pattern produced by two slits when they are illuminated with light from a single narrow slit source.

In the stellar interferometer the two slits are replaced by two mirrors. The disk of the star can be regarded as being equivalent to two narrow sources placed side by side. Each source produces its own interference pattern; the observer sees the patterns superposed on one another. By varying the distance between the two movable mirrors the two interference patterns from the two sides of the star can be made to cancel one another. From the known separation of the mirrors and the effective wave length of the light, the angular diameter of the stars can be computed. Unfortunately, the instrument is sensitive to atmospheric seeing and only the largest stars can be measured by this method. R. Q. Twiss and Hanbury Brown developed another type of interferometer that depends on photon correlations. With it they have measured the angular diameters of Sirius, Vega and several bright stars in the southern hemisphere.

Finally, if the absolute magnitude of a star and its temperature are known, its size can be computed. The temperature determines the rate at which energy is emitted by each unit of area, and the total luminosity gives the total power output. Thus the surface area of the star and its diameter may be estimated. This method is actually the only one available for estimating the dimensions of white dwarf stars. The chief uncertainty is often in choosing the temperature that represents the rate of energy emission.

#### 8. True Stellar Luminosities; Bolometric Magnitudes.—

In theoretical studies of stellar structure and evolution the quantities that must be known are the mass, the radius, the luminosity and the chemical composition. The masses and radii of stars are found directly. The chemical compositions are found only for the surface layers and may differ from those of the interior, at least with respect to the hydrogen-helium ratio, since hydrogen is converted into helium there by thermonuclear processes.

Consider the determination of the true luminosity of the star; *i.e.*, its actual energy output. When the energy radiated by a star is observed, only that portion to which the energy detection device is sensitive and which the atmosphere transmits is obtained. The luminous efficiency for stars like the sun is very high; most of their energy is emitted in spectral regions that can be observed. An M star with a surface temperature of 3,000° K. has an energy maximum (on a wave-length scale) at 10,000 Å; *i.e.*, far in the infrared. A cooler M star radiates most of its energy in the 1.5–3  $\mu$  region. Only a small portion of the actual stellar spectrum is normally observed. Bright cool stars can be observed, however, with the thermocouple. If two dissimilar metals are fastened together to form a continuous circuit and one junction is heated while the other junction remains cool, a small current will flow. The amount of the current will depend on the temperature rise and on the nature of the metals employed in a known fashion. As used at the telescope, one junction of the thermocouple is actually heated by the radiation of the star; hence the sizes of the thermoelements must be very small. Nevertheless, E. Pettit and S. B. Nicholson succeeded in measuring the energy output of certain cool, bright stars such as Betelgeuse, Antares and the long period variables  $\chi$  Cygni and Mira (o Ceti). Corrections for the heavy absorption by molecular bands of water vapour and other constituents of the earth's atmosphere have to be determined and applied. Magnitudes measured with a thermocouple are referred to as radiometric magnitudes.

The problem posed by the hottest stars is more difficult. Whereas there are numerous "windows" in the infrared, the transparency of the earth's atmosphere in the ultraviolet diminishes to zero at 2,900 Å (due to the extinction by ozone). A star whose surface temperature is 20,000° K. or above will radiate most of its energy in the inaccessible ultraviolet. Furthermore, the shape of the energy distribution may deviate widely from that of a black body. Continuous absorption caused by the photo-ionization of the hydrogen atom from its normal (lowest) level reduces the emergent energy flux to a very low value in the region beyond about 920 Å. On the redward (longward) side of this limit the atmospheric gases have a high transparency so that energy can flow outward relatively easily. The only defensible procedure for calculating this energy distribution is to construct a theoretical model of the star's atmosphere that will reproduce

the features of the spectrum that can be observed, particularly the energy distribution in the observable range. If a satisfactory fit can be obtained for the observable part of the spectrum, some estimate of the energy outside the observable range can be made. Nevertheless, the uncertainties are so great that it is a matter of some urgency to obtain observations from outside the earth's atmosphere, either by rockets or by a spectrograph in an orbiting astronomical observatory.

Magnitudes that refer to the total energy radiated by the star, rather than simply the energy emitted over a narrow wave length range, are called bolometric magnitudes. The bolometric corrections required to reduce visual magnitudes to bolometric magnitudes are thus large both for very cool and for very hot stars but are relatively small for stars such as the sun.

### III. DOUBLE STARS

Binary stars are considered in three categories, depending on the mode of observation employed. Visual binaries are objects that can be seen as double stars in the telescope. True doubles, as distinguished from optical doubles, display a common space motion (as revealed by proper motions and radial velocities) and sometimes a common orbital motion as well. Spectroscopic binaries are found from radial velocity observations. A component of such a binary shows a continuously changing velocity with a fixed period; the velocity curve repeats itself exactly from one cycle to the next, and the motion can be interpreted as orbital motion in a close binary. If two stars of approximately equal brightness are observed, as in Mizar, two superposed spectra are found. The lines caused by the individual stars indicate velocity variations that can be interpreted as orbital motion. Eclipsing binaries are detected from the light variations they show when one star passes in front of the other. The best-known example is Algol ( $\beta$  Persei), and good data are known for many such systems.

1. **Visual Binaries.**—The earliest observers of double stars tended to regard them as optical pairs; *i.e.*, as two independent stars seen along the same line of sight. W. Herschel measured a number of these pairs hoping to find evidence for parallactic displacements caused by the earth's orbital motion. Instead, he found displacements in several of these systems indicating a true orbital motion of the stars themselves. In the 19th century a great deal of effort was expended in discovering and cataloguing binary stars. R. G. Aitken (1927) listed 17,180 pairs north of  $-30^\circ$ , E. Kossiter added 7,350 more, while the catalogue of Van den Bos listed 16,000 pairs south of  $-19^\circ$ . The surveys appear to be complete to about the 9th magnitude. The *Index Catalogue of Visual Double Stars* by H. M. Jeffers and Van den Bos (1963) lists essentially all known such objects among its 64,000 systems. Most of these objects show little or no orbital motion, but a few are interesting systems. Visual binaries must be relatively near the sun in order to be detected, whereas spectroscopic binaries and particularly eclipsing binaries can be found at great distances.

The importance of visual binary systems lies in the fact that they permit the determination of stellar masses when the parallax is known. If the period,  $P$ , of the binary system is expressed in years and the radius of the orbit,  $a$  (more accurately its semimajor axis), is expressed in astronomical units, the sum of the masses is given by Kepler's law:

$$m_1 + m_2 = \frac{a^3}{P^2} = \frac{a'^3}{p'^3 P^2} \quad (7)$$

where  $p'$  is the parallax in seconds of arc and  $a'$  is the semimajor axis in the same units. For example, for the well-known binary 70 Ophiuchi,  $P = 87.85$  years,  $p' = 0''.199$ ,  $a' = 4''.55$ , so that  $a = 22.8$  astronomical units, and  $m_1 + m_2 = 1.56$  solar masses. Furthermore, from a measurement of the motions of the two components with respect to the background stars, K. Strand and R. Spong were able to determine the orbit of each star with respect to the common centre of gravity. The mass ratio  $m_2/(m_1 + m_2)$  is 0.422 and the individual masses are 0.90 and 0.66 solar masses. (See ORBIT: Kepler's Laws.)

The faintest known binary for which accurate masses are available is Krüger 60. The two stars, spectral classes M4 and M6,

are separated by 9.5 astronomical units, have a period of 44.5 years and have masses 0.26 and 0.16 that of the sun. The binary with the shortest known period (4.56 years) is H.D. 9,770, for which Dawson finds a mean separation of 4.7 astronomical units and a combined mass of about 5 solar masses.

A number of multiple systems are known. These consist of a close spectroscopic binary and a more distant visual companion. The Mizar-Alcor system is the classical example. Mizar and Alcor (the naked-eye pair) are so far apart that they show no orbital motion, only a common motion through space. Mizar is a visual double, but each component is itself a spectroscopic binary.

In some respects 61 Cygni is the most interesting visual binary system. It was the first star whose distance was measured and the first stellar system found to contain a planet. In the telescope it is a double star consisting of two K-type components separated by 837 astronomical units and moving about one another with a period of 720 years. One of these stars has an invisible companion with a mass  $\frac{1}{10}$  that of the sun which moves about it with a period of about five years. According to all accepted criteria this companion must be regarded as a bona fide planet. Careful examination of the motions of other stars in the neighbourhood of the sun has suggested that other planetary companions may exist. For example, the single star called Ross 614, distant about 13 light-years from the sun, has an invisible companion of  $\frac{1}{10}$  the sun's mass.

**2. Spectroscopic Binaries.**—J. H. Moore and F. J. Neubauer (1948) listed 480 systems for which orbital elements had been determined. Since then, about 150 new systems have been added. Unfortunately, it is not possible to find the semimajor axes or the masses for most spectroscopic binaries since the angle between the plane of the stellar orbit and the plane of the sky cannot be determined. If two spectra can be observed, mass ratios can be determined. If only one spectrum can be observed the best that can be done is to find a quantity called the mass function, which enables one to calculate a lower limit to the stellar masses. If the spectroscopic binary is also observed to be an eclipsing system, the inclination and often the masses of the individual stars can be found.

**3. Eclipsing Binaries.**—An important type of double star is the eclipsing binary, which consists of two close stars moving in an orbit so oriented in space that the light of one may be occulted or eclipsed by the other. Depending on the orientation of the orbit and the sizes of the stars, the eclipses may be total and annular or both eclipses may be partial. The best-known example of eclipsing binaries is the famous  $\beta$  Persei or Algol, which has a period of 2.87 days (interval between eclipses). The brighter star (of spectral class B8) contributes about 92% of the light of the system and the eclipsed star much less than 8%. The system contains a third star that is not eclipsed.

The basic observation datum for an eclipsing binary is the light curve. It displays magnitude measurements of the system over the length of a complete light cycle. Usually the measurements are made by comparing the light of the variable star with that of a nearby comparison star of presumably fixed brightness. Consider fig. 6A. The deep or primary minimum is produced when the star of higher surface brightness is eclipsed. It represents the total eclipse and is characterized by a flat bottom. The shallower secondary eclipse occurs when the star of higher surface brightness passes in front of the other; it corresponds to an annular eclipse (or transit). In a partial eclipse (fig. 6B) neither star is ever completely hidden and the light changes continuously during an eclipse; there are no flat bottomed minima.

An analysis of the shape of the light curve during an eclipse, fol-

lowing the methods of H. N. Russell, gives the ratio of the radii of the two stars,  $r_1, r_2$  and also  $r_1$  in terms of the size of the orbit, the ratio of the luminosities  $l_1, l_2$ , and the inclination of the plane of the orbit to the plane of the sky.

If radial velocity curves are available, i.e., if the system can be observed as a spectroscopic binary as well as an eclipsing binary, additional information is found. In the fortunate circumstances where both velocity curves are observable, the absolute dimensions of the orbit and the sizes, masses and densities of the stars can be found. Furthermore, if the parallax of the system can be found the temperatures of the individual stars may be estimated from their luminosities and diameters. These procedures can be carried out for the faint binary Castor C and the bright B-star  $\mu$  Scorpii.

Light curves of the types as shown in figs. 6A and 6B usually occur in systems where the companions are moderately distant from one another. If the stars are close to one another, additional effects occur that cause the light to vary between eclipses. One of these effects is the tidal distortion produced by the gravitational attraction of one star upon the other. The stars become elongated along the line joining them. Hence, midway between eclipses they appear broadside to the observer and the light of the system is a maximum. (See fig. 6C.)

The reflection effect is exhibited in fig. 6D. Suppose that a small, high temperature star is paired with a larger object of low surface brightness. If the distance between the stars is small, the hemisphere of the cool star presented toward the hotter one will be substantially illuminated. Just before (and just after) secondary eclipse this illuminated hemisphere is pointed toward the observer, and the total light of the system is a maximum. The reflection effect may be large for two stars of greatly differing surface temperature. It vanishes if both stars are of the same surface temperature.

If a light curve is affected by reflection effects and tidal distortion as exhibited in figs. 6C and 6D, it is necessary to correct these variations before the light curve can be analyzed. Such a process is called rectification. If the stars are oblate in shape due to rapid rotation or if the surface brightness is altered as a consequence of the variation of gravity over the surface, it is necessary to allow for these effects in the interpretation of the light curve. Eclipses of oblate stars are necessarily more troublesome to handle than those of spherical stars.

If the disk of the sun is photographed with a high-speed camera, the centre is found to be brighter than the limb. The difference in brightness depends on the wave length of the light used. It is large in the violet, small in the red and almost vanishes in the infrared. This limb darkening arises from the fact that the sun gets hotter toward its core. At the centre of the disk, radiation is received from deeper and hotter layers (on the average) than from the limb. A similar situation holds for the stars; for any given colour of the spectrum the degree of limb darkening will depend on the temperature of the star. Limb darkening must be taken into account in the analysis of the light curve. If it is neglected, the calculated size of the eclipsed star will be too small.

Modern light curves obtained with the photoelectric cell are sometimes so accurate that the tiny differences produced by different degrees of limb darkening can be found and the correct law of darkening as well as the stellar sizes accurately established.

One other effect on the light curves must be mentioned. Some stars move about one another in elliptical orbits. If the major axis of the orbit is at right angles to the line drawn to the observer the stars will take a different length of time to go from primary minimum to secondary minimum than from secondary minimum to primary minimum because they move faster when close together than when far apart (more precisely, the radius vector of the orbit sweeps out equal areas in equal times). Hence the secondary minimum will not fall precisely at the midpoint between primary eclipses (fig. 6E[A]). If the system is observed at a later date the secondary minimum may be symmetrically placed, but now the two eclipses are of unequal duration (fig. 6E[B]). At this time the major axis is pointed toward the observer. One eclipse occurs when the occulting star is moving most rapidly, the other

FIG. 6.—SCHEMATIC LIGHT CURVES OF ECLIPSING BINARIES

when it is moving most slowly. At a still later date the secondary minimum is displaced to the opposite side from the midpoint (fig. 6E[C]). Observation of these effects in any eclipsing system demonstrates that the major axis of the orbit is rotating and establishes the rate of rotation. What causes this rotation of the orbit? A third body might do it and possibly sometimes does, but such a body would produce other effects that could be observed; in most instances it must be concluded that only two stars are present.

Two isolated spherical stars attract one another as point masses and move about one another in elliptical orbits whose orientation remains fixed in space. If, however, the stars are distorted by their mutual tidal attractions, the elliptical orbit will slowly rotate; the speed of rotation will depend in a precisely known fashion on their separation, masses, radii and the degree of mass concentration to the centre. The orbit would turn at a maximum possible speed for stars that were homogeneous; it would not rotate at all for stars whose masses were essentially all concentrated to the centre. All theories of stellar structure predict large mass concentrations toward the centre. (For the sun the central density is about 80 times the mean density.) These predictions can be tested by the eclipsing binaries, and it turns out that in all instances the central condensations are large (as required by theory) but that in some systems the central density may be great. This latter result can be understood in terms of the more modern work on stellar structure. Thus, as Russell called it, the "royal road of eclipses" provides information on the densities, radii and masses of the stars as well as on their internal structures. It is becoming evident that eclipsing stars are going to provide many useful clues to the problem of stellar evolution.

Since the individual stars are often close to one another, extreme examples of tidal distortion, etc., are found. The commonest type of eclipsing binaries, those of the W Ursae Majoris type, are pairs of stars apparently similar to the sun in size but revolving about one another while almost touching.

Although eclipsing binary systems give much detailed data on stars, they do not necessarily give good statistics applicable to isolated single stars. Systems in which a smaller hotter star is accompanied by a larger cooler object are easier to detect than are systems that contain, for example, two main sequence stars. Furthermore, the evolutionary development of two stars near one another does not exactly parallel that of two well-separated or isolated stars.

About 17 or 18 naked-eye eclipsing binaries are known. They include combinations of a variety of stars ranging from objects smaller than the sun (Castor C) to huge supergiants (such as VV Cephei) which would engulf Jupiter and all the inner planets if placed at the position of the sun.

**4. Statistics of Stellar Systems.**—If the known data for all binaries are combined, some interesting statistics emerge. In the neighbourhood of the sun most of the stars are members of binary systems, and some of the nearest single stars are suspected of having companions.

Although some binary systems consist of stars separated by hundreds of astronomical units while others are contact binaries, the most probable binary system is built on the same scale as the solar system. The average separation between components is of the order of ten astronomical units. Studies of the relative masses of the two components show that there is a tendency for the division in mass between two components of a binary to be nearly at random. A mass ratio of about  $\frac{1}{10}$  could occur about 5% of the time, and under these circumstances a solar system might form.

Thus, according to the work of G. P. Kuiper, the formation of double and multiple stars on the one hand and of solar systems on the other are different facets of the same process. A solar system could certainly not be formed by an encounter between two stars. Rather, planets may be produced by a process akin to that depicted in the nebular hypothesis of Laplace except that most of the mass and angular momentum is swept out of the system. Only a small fraction of the original material is retained as planets. Solar systems may be frequent in the earth's galaxy; perhaps 100,000,000 stars have bona fide planets.

#### IV. STELLAR VARIABILITY

A fair number of the stars in the sky are intrinsically variable; that is, their total energy output fluctuates with time. Some of these stars were found by accident, but many were detected as a result of carefully planned searches. Variable stars are important in astronomy for a number of reasons. They usually appear to be stars at critical or short-lived phases of their evolution; detailed studies of their light and spectral characteristics, spatial distribution and association with other types of stars may provide important clues to the life histories of various classes of stars. Certain kinds of variable stars such as Cepheids and novae are extremely important in that they make it possible to establish the distances of remote stellar systems such as the Magellanic Clouds and some of the nearer extragalactic nebulae or external galaxies (see NEBULA: *The Extragalactic Distance Scale*). The principle is this: If the intrinsic luminosity of a particular kind of variable is known and this kind of variable star can be recognized in a distant stellar system, the distance of the latter can be estimated from a measurement of the apparent luminosity. If  $l$  is the apparent brightness,  $L$  the intrinsic brightness corresponding to the standard distance,  $R$ , of 10 parsecs or 32.6 light-years,  $l/L = R^2/r^2$  where  $r$  is the distance of the star. If the stellar brightness is expressed in magnitudes

$$y = m - M = 5 \log r - 5 \quad (8)$$

If there is absorption of light in space, the apparent magnitude,  $m$ , must be corrected for the amount of extinction. (See INTER-  
STELLAR MATTER.)

The most important classes of variable stars are the following:

Cepheids and RR Lyrae stars	Supernovae
Long-period variables	R Coronae Borealis stars
Semiregular variables	$\beta$ Canis Majoris stars
Irregular red variables	T Tauri stars
Novae	Spectrum and magnetic variables
SS Cygni stars	Flare stars

The long-period variables, the novae and the Cepheids were the types earliest recognized. The first four classes probably owe their variability to pulsation. The next three are sometimes referred to as catastrophic variables, while the remaining five types owe their variability to less dramatic but perhaps just as bizarre causes.

The spectrum and magnetic variables, spectral class A, show small amplitudes of light variation but pronounced spectroscopic changes. Their spectra are characterized by strong lines of heavy metals, particularly rare earths, which vary in intensity in a periodic fashion. H. W. Babcock discovered that these stars have strong magnetic fields, up to 30,000 gauss. Not all magnetic stars are known to be variable in light, but the variable ones seem also to possess variable magnetic fields.

The T Tauri variables are dwarf stars of spectral classes G and K. They invariably fall in regions of high obscuration; i.e., dense clouds of absorbing material. Their changes in brightness are erratic; some, such as R Monocerotis, are associated with small fan-shaped nebulae. Their spectra show bright lines and washed-out absorption lines suggesting that they are rapidly spinning objects in clouds of diffuse material. Flare stars are cool dwarfs (spectral class M) that display flares apparently like those of the sun except that they fade away much more rapidly.

Various lines of evidence suggest that these stars are objects either recently formed or in the process of formation from the interstellar medium.

The  $\beta$  Canis Majoris stars are high temperature (spectral class B) stars that often show complicated variations in spectral line shapes and intensities, velocity curves and light. They often have two periods of variation so similar in duration that complicated interference or "beat" phenomena are observed.

R Coronae Borealis variables are giant stars of about the sun's temperature whose atmospheres are characterized by excessive quantities of carbon. Their brightness remains constant until suddenly the star dims by several magnitudes and then slowly recovers its original brightness; the star's colour remains the same during the changes in brightness. The dimmings occur in a random fashion. L. Berman and J. A. O'Keefe have suggested that the

### STAR CHART OF NORTH POLAR HEMISPHERE

Most stars visible to the naked eye and north of the celestial equator are shown in this chart. The North Star, Polaris, is shown slightly to the right of the north celestial pole. This star is not exactly true north. At the bottom of the chart is the first magnitude star Betelgeuse in the constellation of Orion. This was the first of the large stars to have its diameter measured. At the left of the north celestial pole is the "Great Bear" with its pointer stars in line with the North Star. In the upper part of the chart is the constellation Hercules toward which the entire solar system is moving at the rate of about 12 miles per second. Owing to the rotation of the earth on its axis, all stars shown in this chart appear to rotate around the north celestial pole in a counterclockwise direction.

### STAR CHART OF THE SOUTH POLAR HEMISPHERE

Showing all of the principal stars visible to the naked eye found south of the celestial equator. To the left of the south celestial pole in the chart is the Southern Cross (Crux). Notice the 2 pointers,  $\alpha$  and  $\beta$  Centauri, just below Crux;  $\alpha$  Centauri is a triple star, one of whose members is the nearest star to the earth. Below the south celestial pole and slightly to the left is Scorpius which contains the supergiant red star Antares, which is one of the largest stars that has been measured up to the present time. It is visible from practically every point in the inhabited world. To the right of the south celestial pole is Fornalhaut, a first magnitude star in the constellation "The Southern Fish." Sirius, of the constellation "The Big Dog" and the brightest star in the sky, is near the top of the chart. All stars shown in chart appear to revolve around the south celestial pole in a clockwise direction due to the rotation of the earth on its axis

clue to the variability was to be sought in the huge concentrations of carbon.

At times the carbon vapour literally condenses into soot, and the star is hidden until the smog blanket is evaporated. Similar veiling may sometimes occur in other stars, particularly the long-period variables, thus providing an engaging problem in chemistry.

The novae or temporary stars are discussed in detail elsewhere (see NOVA AND SUPERNOVA) so only a few summarizing remarks need be made here. Normally they are small blue stars much fainter than the sun although very much hotter. When an outburst occurs, the star may brighten very suddenly, ten magnitudes or even more. Thereafter it fades, sometimes slowly and sometimes rapidly. The rate of fading is connected with the brightness of the nova. The brightest novae, which reach absolute magnitudes about  $-8$ , fade the most rapidly, whereas a typical slow nova, which reaches an absolute magnitude  $-5$ , may take ten times as long to decline in brightness. The changes in light are accompanied by pronounced spectroscopic changes that can be interpreted as arising from an ejected shell that dissipates slowly in space. The mass of the shell is presumably rather small, comparable with the mass of the earth and presumably much smaller than the mass of Jupiter. Presumably only the outer shell of the star is affected; the main mass settles down until a new outburst appears. The existence of repeating novae such as T Coronae Borealis suggests that perhaps all novae repeat at intervals ranging from thousands to perhaps millions of years. B. Kukarkin and P. P. Parenago suggested that the amplitude of the outbursts is probably connected with the intervals between them in the sense that the larger the explosion the longer the interval. Associated with novae are stars such as Z Andromedae which in their normal condition show remarkable spectra combining the characteristics of cool M-type stars, gaseous nebulae and hot stars with bright emissions of hydrogen and helium. They occasionally show novae-like outbursts. Several novae are close binary stars, and perhaps all of them are. It has been suggested that dwarf contact binaries of the W Ursae Majoris type become novae late in their evolution.

Stars of the SS Cygni type show novae-like outbursts but with a much smaller amplitude and with intervals between outbursts of a few months to about a year. These novae-like stars often are binaries, and it may be that the development of this particular type of star occurs in a close binary system.

Supernovae represent quite a distinct type of phenomenon. These stars become ten or even several hundred million times as bright as the sun and then gradually fade away. Such outbursts occur once every 400 or 500 years in a given galaxy, but three are known to have occurred in our own galaxy—Tycho's star of 1572, Kepler's nova of 1604 and the Crab Nebula. The latter object has been identified with a temporary star observed in China and Japan in 1054 and now observed as a strong radio source and an unusual optical object. Supernovae are believed to be stars that actually explode as a consequence of runaway thermonuclear reactions. (See ASTRONOMY: Radio Astronomy.)

Stellar pulsations are believed to account for the variability of the Cepheids, the long-period variables, the semiregular variables and even the irregular red variables. Of this group the Cepheids have been studied in greatest detail, both theoretically and by observation. These stars are regular in their behaviour; some repeat their light curves with great faithfulness from one cycle to the next.

Much confusion existed in the study of Cepheids until it was recognized that there existed two families of stars now denoted as population types I and II. Population type I is that associated with the spiral arms of this and other galaxies. It contains stars of all ages, from those in the process of formation to defunct white dwarfs. The best examples of type I populations are galactic or open clusters such as the Pleiades or the beautiful double cluster in Perseus ( $\eta$  and  $\chi$  Persei). Population type II comprises the stars of the central bulge of our galaxy, elliptical nebulae, globular clusters and most of the stars moving between the spiral arms. These stars are all very ancient; their ages are probably more than 7,000,000,000 years.

Some writers employ a more elaborate classification. The globular clusters and central bulge of the galaxy with their related stars comprise population type II. The stars between the spiral arms and most of those above and below the galactic plane are called the "disk population." Population I is divided into an old population I (which includes the sun) and a young population I (stars a few tens of millions of years old or less). The older classification system is retained for this discussion.

Corresponding to these population types are separate species of variable stars. The Cepheids belonging to the spiral arm population (type I) are characterized by regularity in their behaviour. They show continuous velocity curves indicative of a regular pulsation. They exhibit a relation between period and luminosity in the sense that the longer the period of the star the greater its intrinsic brightness. This period-luminosity relationship has been used to establish distances of remote stellar systems. Cepheids are also found in the type II population, e.g., away from the Milky Way in globular clusters, but these type II Cepheids exhibit some very different properties from classical type I Cepheids. They are bluer than classical Cepheids of the same period and their light curves have different shapes. Studies of the light and velocity curves indicate that shells of gas are ejected from the stars as discontinuous layers that later fall back toward the surface. Most disappointing of all, however, is the fact that these stars exhibit no well-defined relation between period and luminosity. Consequently, they are worthless as distance indicators. The distance of a Cepheid in a distant stellar system can be determined only if it is known to be a classical Cepheid.

Closely associated with type II Cepheids are cluster-type or RR Lyrae variables. All these stars have periods less than a day, and there appears to be no correlation between period and luminosity. Their absolute magnitudes are about  $+0.6$ ; i.e., they are about 47 times as bright as the sun. They are useful for determining distances of star clusters and some nearby external galaxies, since their short periods permit them to be detected readily.

The possibility of stellar pulsations was suggested long ago by A. Ritter; direct applications to Cepheids were made first by H. Shapley, while Sir Arthur Eddington developed the theory necessary for the problem. If all stars have roughly the same kind of internal structure, the period and density are related by the condition

$$P\sqrt{\rho} = \text{constant} \quad (9)$$

where the value of the constant depends on the internal structure; i.e., the "model" of the star. Since the masses of Cepheids are not known, there is no direct test of this hypothesis.

Furthermore, while the star pulsates, all parts of the inner core move in synchronism, but the outer parts get out of step or lag behind the pulsation of the inner core.

What causes the pulsations is not known, and all that can be asserted is that the mechanism that generates them has a period that exactly matches the free period of oscillation of the stars.

The long-period variables also probably owe their variations to pulsations. Here the situation is complicated by the vast extent of their atmospheres. These stars appear to fall into two groups: (1) those with shorter periods (of the order of 200 days) tend to be associated with the type II population; (2) those of periods of the order of a year belong to the type I population. These stars are invariably red cool giant and supergiant stars of spectral classes M (normal composition), R and N (carbon rich), or S (heavy-metal rich). The range in visual brightness may be a hundredfold, but the range in total energy output is much less because at very low temperatures ( $1,500^\circ\text{K.}$ – $3,000^\circ\text{K.}$ ) most of the energy is radiated as heat rather than as light. A slight change in temperature can produce a huge change in the output of visible radiation. At these temperatures, compounds and probably solid particles are formed so that the light change may be profoundly affected by chemical as well as physical factors.

Red semiregular variables such as the RV Tauri stars show complicated light and spectrum changes. They do not repeat themselves from one cycle to the next; their behaviour suggests a simultaneous operation of two or more modes of oscillation.

Betelgeuse is an example of an irregular red variable. In these stars the free period of oscillation does not coincide with the periodicity of the driving mechanism.

Variable stars may provide very important clues to stellar evolution. Probably all of them represent more or less ephemeral phases in the evolution of a star. Aside from such catastrophic events as a supernova in which an entire star is torn asunder, some phases of stellar variability may be of such brief duration as to permit detectable changes during an interval of 50 or 100 years. Other stages may require many thousands of years. For example, the period of  $\delta$  Cephei has not changed by a detectable amount since its variability was discovered.

### V. CORRELATIONS BETWEEN LUMINOSITY, SPECTRUM, AND MASS

Some of the most important generalizations concerning the nature and evolution of stars can be made from correlations between different observable properties and from certain statistical results. One of the most important of these correlations concerns the spectrum and luminosity.

If one plots the absolute magnitudes of the stars (or their intrinsic luminosities on a logarithmic scale) against the spectral types, as Russell was the first to do in 1913, the stars do not fall at random on the diagram but tend to congregate in certain restricted domains (see fig. 7). Most of the congregated stars are dwarfs belonging to what is called the main sequence. These stars range from hot blue objects 10,000 times (or more) brighter than the sun, down through white A stars such as Sirius, yellow-white F stars such as Procyon, through the sun, down to orange K stars such as  $\epsilon$  Eridani, and finally to faint red dwarfs thousands of times fainter than the sun. The sequence is continuous, the luminosities fall off smoothly with decreasing surface temperature, the masses and radii decrease but at a much slower rate and the densities gradually increase.

The second group of stars to be recognized was the giants, objects such as Capella, Arcturus and Aldebaran, yellow, orange or red stars about 100 times as bright as the sun and with diameters of 10,000,000 or 20,000,000 mi. The supergiants include stars of all spectral classes; they show a big spread in intrinsic brightness; some even approach absolute magnitudes  $-7$  or  $-8$ . Some red supergiants such as the variable VV Cephei exceed in size the orbit of Jupiter or even Saturn, although most of them are smaller. The short-lived supergiants are rare in space; their great luminosity enables them to be seen at great distances.

The subgiants are stars that are redder and larger than main sequence stars of the same luminosity. Most of the known ex-

amples are found in close binary systems, particularly in eclipsing systems where conditions favour the detection of doubles in which a subgiant is paired with a main sequence star.

The white dwarfs comprise a group of stars falling about ten magnitudes below the main sequence. Numerically, they exceed the representatives of any group except the main sequence. These objects are of interest for several reasons, not the least of which is that they represent the last stage in stellar evolution, the last feeble glow of a dying star. Their masses are comparable with that of the sun; their densities exceed anything that can be produced in the laboratory. The first of these remarkable objects to be recognized was the companion to Sirius, originally detected by its gravitational attraction upon the larger, brighter star and only later discovered visually as a faint object, about 10,000 times fainter than Sirius. Its mass was about equal to that of the sun. Later work showed that the colour and spectrum of this star corresponded to about spectral class A; i.e., it had a surface temperature of  $8,000^\circ\text{K}$ . or  $10,000^\circ\text{K}$ . Hence the rate of emission of energy from the surface must be much greater than that of the sun. Since it was about 500 times fainter than the sun, it must have a much smaller surface area and therefore a much smaller volume. Thus the density would have to be a great deal higher than that of the sun. The average density is about 10,000 times that of water. Under these conditions the electrons are nearly all stripped off the atoms and form what is called a degenerate gas. Such material has remarkable properties. It does not obey the ordinary gas laws and is an almost perfect conductor of heat.

Notice that the spectrum luminosity diagram has numerous gaps. For example, above the white dwarfs and to the left of the main sequence there are very few stars. The main sequence and the giants are separated by a gap named after E. Hertzsprung, who was the first to clearly recognize (in 1911) the difference between main sequence and giant stars. The actual concentration of stars in different parts of the diagram changes considerably. Highly luminous stars are rare; those of low luminosity are very numerous.

One feature of fig. 7 must be emphasized. It applies to the spiral arm in the neighbourhood of the sun and represents what would be obtained if Russell-Hertzsprung diagrams were constructed for a large number of open clusters such as  $\delta$  and  $\chi$  Persei, the Pleiades, Coma Berenices and the Hyades and added all together. It includes very young stars (only a few million years old) as well as very ancient (8,000,000,000 or 9,000,000,000 years old) stars. This spiral arm population is called by Walter Baade a type I population to distinguish it from the type II population associated with the globular clusters and the central bulge of the galaxy.

Fig. 8 exhibits the type of spectrum-luminosity relation characteristic of the globular clusters, the central bulge of the galaxy and the elliptical external galaxies. Since these systems are very remote from the observer, the stars are very faint and their spectra cannot be observed. Instead it is necessary to resort to measurements of their magnitudes and colours. Since the colours are closely related to the spectral classes, equivalent spectral classes may be used, but it is to be noted that stellar colours, not spectral classes, are observed in this instance.

The difference between fig. 7 and 8 is striking. In fig. 8 there are no supergiants, and instead of falling at  $M_v = 0.0$  the giant branch starts around  $-3.5$  for very red stars and forms a continuous sequence until an absolute magnitude of about  $-1$  is reached. Then there is a band of stars, all about the same colour, proceeding downward (i.e., to fainter stars) to about  $M = +3$ . The giant branch is then connected to the main sequence at about  $+3.5$  by a narrow band. The main sequence extends to fainter and redder stars in much the same way as in the spiral arm population. The main sequence ends just above the sun, however, and does not extend up through the A, B and O spectral classes. Occasionally a few stars are found in the region normally occupied by the main sequence.

The horizontal branch falls near magnitude 0 and fills the Hertzsprung gap. The striped area in fig. 8 indicates the domain of the RR Lyrae stars. M. Schwarzschild found that every short-

FIG. 8.—COLOUR-MAGNITUDE ARRAY FOR A TYPICAL TYPE II POPULATION AS REPRESENTED BY A GLOBULAR CLUSTER

Absolute visual magnitude is plotted against the colour index of the star in the sense  $C.I. = M_v - M_b$ . It is assumed that the RR Lyrae stars have an absolute magnitude of  $+0.6$ . Equivalent spectral types are plotted at top of diagram

period cluster variable fell in this small region of the diagram. Conversely, every star in this range of magnitude and colour has been found to be a variable. The horizontal branch extends beyond the RR Lyrae stars; among these blue stars are found novae and the nuclei of planetary nebulae. Not all globular clusters show identical colour-magnitude arrays. Some clusters such as M3 have many RR Lyrae stars; others such as M13 have very few. Some have numerous giants; others have numerous blue stars on the horizontal branch. In M92 the whole giant branch is bluer than in M13.

Spectroscopic observations indicate that stars in globular clusters do not all have the same hydrogen-metal ratios. Among the extreme examples of Baade's population type II stars found in the neighbourhood of the sun are the so-called subdwarfs. The abundance of metals in these stars is perhaps  $<1\%$  to  $10\%$  that in the sun. Stars of a somewhat similar composition are found in certain globular clusters, particularly M92. Many globular clusters appear, however, to have compositions intermediate between that of the sun and these extreme subdwarfs.

Not all stars of Baade's population type II are confined to globular clusters and the central bulge of the galaxy. Many are found scattered throughout the galactic system; some are encountered in the neighbourhood of the sun. High velocity stars are of Baade's type II, but not all type II stars display a high velocity. Numerically the ancient type II population probably greatly exceeds the type I population in our galaxy.

Another item of great statistical interest is the relationship between the luminosities of the stars and their frequency of occurrence. The naked-eye stars are nearly all brighter than the sun. On the other hand, if a census is taken of the known stars within 20 light-years of the sun it is found that the opposite situation is true. Most of these stars are fainter than the sun (see Table II). The bright stars are easily seen at great distances; the faint ones can be detected only if they are close. For example, a star of absolute magnitude  $-4.0$  would be visible to the unaided eye at a distance of 1,000 parsecs, whereas a star of magnitude  $+11$  would be visible only if it fell closer than 1 parsec. That is, only if stars of magnitude  $+11$  were 1,000,000,000 times more abundant in space than stars of magnitude  $-4$  would one observe them in equal numbers, provided one observed all stars to some fixed limit of apparent brightness.

Table III gives the relation between the numbers of stars and their luminosities for stars in the neighbourhood of the sun. Thus, in a cube 100 parsecs on a side one could expect to find about 18

stars between the 4th and 5th magnitude and 80 stars between the 10th and 11th, but there would be less than one chance in a thousand of finding a star brighter than  $-5$ . The fainter end of the luminosity function is not well established. It appears to have a maximum near the 14th magnitude and to fall off to yet fainter stars in a fashion not yet established.

The luminosity function depends on the part of the galaxy under consideration. The neighbourhood of the sun includes examples of both populations type I and II. For a pure population type II the luminosity function will differ substantially from that of a pure population type I. Also, the luminosity function changes with distance from the galactic plane and, of course, with the age of the sample studied.

One of the most important correlations is that between mass and luminosity for main sequence (dwarf) stars. If one takes the visual binaries for which good parallaxes and masses are known and plots the mass of each star against its bolometric luminosity one finds that the points tend to fall on a curve which shows that the more massive stars are simultaneously the more luminous. Discussions by various astronomers show that for stars in the neighbourhood of the sun the luminosity is very nearly proportional to the fourth power of the mass, the actual relation being

$$L \approx \text{constant } M^{3.8} \quad (10)$$

where  $L$  and  $M$  are expressed in terms of the luminosity and mass of the sun respectively. The constant is very nearly unity; i.e., the sun lies on the mass-luminosity curve defined by the nearby stars. The relationship is not a precise one, because for each mass there does not correspond a unique luminosity. In fact, a small range in luminosity exists for main sequence stars as a consequence of stellar evolution. A range also seems to exist because of chemical composition differences.

The mass-luminosity correlation is derived from visual double star systems and applies to main sequence stars. It fails for giants and supergiants and for the faint components of eclipsing binaries that usually are subgiants. Also it does not apply to any of the stars in a globular cluster brighter than absolute magnitude  $M = +4.0$ , or, in other words, stars other than those that fall on the main sequence.

TABLE III.—Relation Between Numbers of Stars and Their Luminosities

Absolute magnitude	Numbers of stars	Absolute magnitude	Numbers of stars
-5.5	0.00040	+3.5	10.5
-4.5	0.0024	+4.5	18.5
-3.5	0.0085	+5.5	27.0
-2.5	0.030	+6.5	36.0
-1.5	0.093	+7.5	46.0
-0.5	0.270	+8.5	56
+0.5	0.80	+9.5	68
+1.5	2.20	+10.5	80
+2.5	5.2	+11.5	91

Source: Compiled from data of W. J. Luyten and P. J. van Rhijn.

The white dwarfs have long been known to fall off the mass-luminosity correlation; these stars are abnormally faint for their masses. They represent defunct stars near the end of their evolution, objects which have exhausted their nuclear fuel and presumably now are simply cooling down.

The mass-luminosity correlation was predicted theoretically by Eddington. It is a general relationship which holds for all stars built on essentially the same internal density and temperature distributions: i.e., the same models. The types of stars for which it fails are those built on models different from those appropriate for main sequence stars.

## VI. STELLAR STRUCTURE

The internal pressures, temperatures and densities of main sequence stars and particularly white dwarfs can be calculated with greater confidence than can the internal temperature and density of the earth. This is true because of the following basic physical principles:

First, we suppose that the star is in mechanical equilibrium. That is, at each point the pressure exactly balances the weight of the overlying layers. If  $g$  is the acceleration of gravity,  $\rho$  is the

density and  $\Delta P$  the increase in pressure over a small increment in distance  $\Delta r$ , then

$$\Delta P = g\rho\Delta r \quad (11)$$

A second equation expresses the continuity of mass. That is, if  $M_r$  is the mass of material lying in a sphere within a radius  $r$ , the amount of mass added when one goes a distance  $\Delta r$  through a shell of volume  $4\pi r^2\Delta r$  is:

$$\Delta M = 4\pi r^2\rho\Delta r \quad (12)$$

The third relation involved is what is called an equation of state; it expresses the relation between the pressure, density and temperature of the material. Throughout the body of the star the material is entirely gaseous. In most stars it obeys closely the perfect gas law:

$$P = \frac{\Re\rho T}{\mu} \quad (13)$$

Here  $P$  is the pressure (usually expressed in dynes per square centimetre although it may also be given in atmospheres),  $\rho$  is the density (g. per cubic centimetre) and  $T$  is absolute temperature ( $^{\circ}$  K.).  $\Re$  is the gas constant (defined for a gram molecule of material). Finally,  $\mu$  is the molecular weight: 2 for molecular hydrogen, 4 for helium and 56 for iron vapour. In the interior of a typical star, however, almost all of the material is completely ionized. Under these circumstances the hydrogen molecules are not only broken down into individual atoms but the atoms themselves are broken down (ionized) into protons and electrons. Hence, the molecular weight of ionized hydrogen is  $\frac{1}{2}$ , since the average mass of a proton and an electron is  $\frac{1}{2}$  on the atom weight scale. On the other hand, a completely ionized helium atom contributes a mass of 4 with 2 electrons of negligible mass; hence the molecular weight is  $\frac{4}{3}$ . A completely ionized nickel atom contributes one nucleus of mass 58.7 plus 28 electrons; hence, its molecular weight is  $\frac{58.7}{29} = 2.02$ . Since stars contain a preponderance of hydrogen and helium which are completely ionized throughout the interior,

$$\mu = \frac{1}{2X + (3/4)Y + \alpha(1 - X - Y)} \quad (14)$$

where  $X$  and  $Y$  are the concentrations by weight of hydrogen and helium, respectively, and  $\alpha$  is nearly  $\frac{1}{2}$ . Hence the molecular weight will depend critically on the chemical composition, particularly on the ratio of hydrogen to helium and the total content of heavier material.

If the temperature is sufficiently high, the radiation pressure, which is numerically equal to one-third of the energy density, must also be taken into account. Hence the total equation of state is

$$P = P_g + P_r = \frac{\Re\rho T}{\mu} + \frac{1}{3}aT^4 \quad (15)$$

where  $a = 7.56 \times 10^{-15}$  is called the radiation density constant. Set  $\mu = 2$  (upper limit),  $\rho = 1.4$  g. per cubic centimetre (mean density of sun) and calculate the temperature at which the radiation pressure would equal the gas pressure. With  $\Re = 8.32 \times 10^7$  the required temperature is 28,000,000 $^{\circ}$ , which is much hotter than the centre of the sun, where the density is about 100 times that of water. Hence radiation pressure in the sun may be neglected, but it cannot be neglected in hotter, more massive stars. Radiation pressure may indeed set an upper limit to stellar luminosity (as Eddington suggested long ago).

Certain stars, notably the white dwarfs, do not obey the perfect gas law. Instead, the pressure is almost entirely contributed by the electrons, which obey a law called the degenerate gas law. The pressure and density are related by a law of the form

$$P = 9.9 \times 10^{13} \left( \frac{\rho}{\mu} \right)^{\frac{5}{3}} \quad (16)$$

where  $\mu'$  is the average mass per free electron of the totally ionized gas. Notice that the temperature does not enter at all.

At yet higher densities the equation of state becomes more intricate, but S. Chandrasekhar showed in elegant fashion how even this complicated equation of state could be employed in the calculation of the internal structure of these white dwarf stars. There are probably better models for the white dwarfs than for most other objects.

In order to make further progress it must be known how energy is transported in the interior. Thermal conduction cannot play any significant role inasmuch as the heat conductivity of gases is very low. One mode of transport is the actual flow of radiation through the star. Starting out as X-rays the radiation is gradually "softened" as it works its way to the surface to emerge as ordinary light and heat. The rate of flow of radiation is proportional to the temperature gradient,  $\Delta T/\Delta r$ , the rate of change of temperature with distance. Specifically,

$$\text{Rate of energy flow} = \frac{4acT^3}{3\kappa\rho} \left( \frac{\Delta T}{\Delta r} \right) \quad (17)$$

Here  $a$  is the radiation density constant,  $c$  is the velocity of light,  $\rho$  is the density and  $\kappa$  is a measure of the opacity of the material. That is, the larger the value of  $\kappa$ , the smaller the transparency of the material and the steeper the temperature fall required to push the energy outward at the required rate. The opacity  $\kappa$  can be calculated for any temperature, density and chemical composition. The actual computations are difficult;  $\kappa$  is found to depend in a complicated way on the density and temperature.

In the outer layers of the sun and particularly in certain giant stars, transport of energy takes place by quite another mechanism: large-scale mass motions of gases or convection. Large volumes of gas deep within the star become heated, rise to higher layers and mix with their surroundings, thus releasing great quantities of energy. The extremely complicated flow patterns cannot be followed in detail, but when convection occurs there exists a relatively simple relation between pressure and density, namely

$$P = K\rho^{\gamma} \quad (18)$$

where  $\gamma$  is  $\frac{5}{3}$  for a completely ionized gas and  $K$  is a constant of proportionality.

Finally, the most fundamental property of stars must be considered, namely, that they radiate energy and hence must derive their energy from sources within themselves. For normal main sequence stars such as the sun, the source of the energy lies in the conversion of hydrogen into helium. The reaction believed to occur in the sun is the proton-proton reaction proposed first by H. Bethe and R. Critchfield and later revised by C. C. Lauritsen and W. A. Fowler and independently by E. Schatzman. The reactions are:

Two protons collide to form a deuteron (heavy hydrogen nucleus) with the liberation of a beta ray, or positive electron (positron). This positive electron meets a negative electron and the two annihilate one another with the liberation of energy in accordance with the Einstein relation

$$E = mc^2 \quad (20)$$

where  $m$  is the mass annihilated,  $c$  is the velocity of light and  $E$  is the energy released. Here  $m$  is the mass of the two electrons. The annihilation energy amounts to 1.02 Mev. This process is one of low probability, and many proton-proton collisions occur before a positive electron is created.

Next, a proton collides with the deuteron to form the nucleus of the light helium atom of atomic weight 3. Finally, two light helium nuclei collide to form a nucleus of ordinary helium and two protons. In the course of this reaction four protons have been consumed to form one helium nucleus, and two negative electrons have perished.

The mass of four hydrogen atoms is  $4 \times 1.00797 = 4.03188$ ; that of a helium atom is 4.0026. Hence 0.02928 atomic mass units or 0.7% of the original mass has disappeared. Some of

this has disappeared in the form of the elusive neutrinos, but most of it has been converted into radiant energy. To keep shining at its present rate, the sun has to convert 674,000,000 tons of hydrogen into 670,000,000 tons of helium every second. More than 4,000,000 tons of matter literally disappear into radiation every second. The rate of energy generation according to the proton-proton reaction varies as about the fourth power of the temperature.

In hotter stars the principal source of energy is the carbon cycle, in which hydrogen is converted into helium with carbon serving as a catalyst. The reactions are as follows: First, a carbon nucleus captures a hydrogen nucleus or proton to form a nucleus of  $N^{13}$ , thus

A gamma ray is emitted in the process. The light  $N^{13}$  nucleus is unstable, however. It emits a positive electron which encounters a negative electron and the two annihilate one another. The resulting  $C^{13}$  nucleus is stable. Eventually the  $C^{13}$  nucleus captures another proton, forms  $N^{14}$  and emits another gamma ray.

The  $N^{14}$  is stable, ordinary nitrogen. When it captures a proton to form  $O^{15}$ , the resulting nucleus is unstable against beta decay. That is, it emits a positive electron.

That is, the  $O^{15}$  nucleus emits a positive electron that meets a negative electron and is annihilated. Eventually the  $N^{15}$  nucleus encounters a fast-moving proton and captures it. It might be supposed that at this point a nucleus of ordinary  $O^{16}$  would be formed. Actually this process occurs rarely, the favoured reaction being

The capture of the proton causes the resultant nucleus to break down into the original  $C^{12}$  nucleus and an alpha particle, or helium nucleus of mass 4. Thus, the original carbon nucleus reappears, and the four protons that have been added permit the formation of an alpha particle. The same amount of mass has disappeared although a different fraction of it may have been carried off by the neutrinos.

The physicist with his particle accelerator produces these reactions by firing protons with hundreds or even thousands of kilovolts of energy at targets of graphite or nitrogen compounds. Since both the heavy nucleus and the proton have positive charges, they repel one another by Coulomb's law. Occasionally the particles come close enough together for short-range attractive forces in the nucleus to allow the proton to stick. The higher the energy involved, the greater the probability of proton capture.

In the interior of a star the particles are moving rapidly about as a consequence of their high energies. Once in a while a proton is directed sufficiently close to a nucleus for it to be captured so that a nuclear reaction can occur. Only the protons of very highest energy (many times the average energy in a star like the sun) are capable of producing reactions. Since the energies of the protons depend very strongly on the temperature, the rate of energy production rises steeply with the temperature. The temperature dependence is much steeper for the carbon-nitrogen cycle than it is for the proton-proton reaction.

The hottest stars of the main sequence (and probably also the supergiants) shine with energy produced by the carbon cycle. The faint red dwarf stars use exclusively the proton-proton reaction, whereas the sun shines mostly by the proton-proton reaction but has some contribution from the carbon cycle.

With the aid of the aforementioned mathematical relationships including the law of energy generation it is possible to attack the problem of stellar structure. In the first approximation it is usually assumed that the stars have a uniform chemical composition

throughout their interiors. This assumption simplifies the calculations greatly, but it has to be abandoned when stellar evolution is concerned. The mathematical and physical relationships involved are such that solutions expressible in algebraic form or as functions of types known to mathematicians are not obtainable. The solutions have to be carried out numerically by a step-by-step process known as mechanical integration. At the surface the pressure and density vanish; at the centre of the star the pressure, density and temperature must remain finite. A frequent procedure is to carry the calculations from the surface inward and from the centre outward, the condition being that the two solutions must fit together, giving the same pressure, density, temperature, etc., when they meet. One of the most important generalizations that can be drawn from such calculations is the famous mass-luminosity relation, discovered by Eddington. It may be written in the form

$$L = C \frac{M^a \mu^b}{R^c} \quad (25)$$

where  $M$  is the mass of the star,  $\mu$  the molecular weight, and  $R$  the radius.  $C$  is a constant that depends on the particular numerical choice of physical relationships involved, for example, on the exact value of the opacity. Here  $a$ ,  $b$  and  $c$  are constants that also depend for their precise values on the exact form of the law of opacity, for example. Numerically,  $a$  is of the order of 5,  $b$  of 7 or 8 and  $c$  about 1.5. This means that the luminosity depends steeply on the mass but even more steeply on the molecular weight and therefore on the chemical composition. A relationship of this type must exist because the greater the mass, the greater the internal pressure and, therefore, by equation (15), the greater the internal temperature. The temperature gradient likewise increases and, therefore, so does the outward flux of energy.

Still another relationship between luminosity, mass, radius and molecular weight is derived from temperature, density distribution and the known nuclear energy sources. For a star shining on the carbon cycle a relation is obtained of the form

$$L = B(1 - X - Y)\mu^d \frac{M^e}{R^f} \quad (26)$$

where  $X$  and  $Y$  are the proportions by weight of hydrogen and helium, respectively. Here  $d$  is of the order of 20,  $e$  about 22 and  $f$  about 23 since the carbon cycle depends on a high power of the temperature. This equation is called the energy output relation and was used by Schwarzschild to demonstrate how, for a given model, one could obtain both the hydrogen and the helium contents.

Calculations of stellar models have occupied the attention of astronomers for a number of years. For young main sequence stars it is possible to obtain satisfactory solutions with a chemical composition that is uniform throughout the star. In the sun and fainter stars of the main sequence energy is transported throughout the outer layers by convection currents whereas in the deep interior, energy is transported by radiation. Among the hotter stars of the main sequence the reverse appears to be true. The deep interiors of stars which derive their energy primarily from the carbon cycle are in convective equilibrium whereas in the outer parts the energy is carried by radiation. It is possible to reproduce the observed masses, luminosities and radii of main sequence stars with reasonable assumptions concerning their chemical composition.

Chemically homogeneous models of giant and supergiant stars cannot be constructed. That is, if it is assumed that a yellow giant star such as Capella is built on the same model as the sun or other main sequence stars, the central temperature will turn out to be so low that no known nuclear process can possibly supply the observed energy output. Progress has been made only by assuming that these stars were once main sequence objects which, in the course of their lives, exhausted the hydrogen in their deep interiors. As a consequence these stars developed inert cores composed mostly of helium, which is the ash of the hydrogen burning processes. Since helium is impervious to nuclear reactions at the tens of millions of degrees and the densities likely to prevail in these

interiors, no thermonuclear energy could be obtained from these depleted cores. Energy is assumed to be generated in a thin shell surrounding the inert core and is presumably produced by the carbon-nitrogen cycle. Such models are called shell-source models. As the star uses up more and more of its hydrogen supply, the core increases in mass but the outer envelope of the star continues to expand in size. These shell-source models appear to be capable of explaining the observed luminosities, masses and radii of giant and supergiant stars.

The depletion of hydrogen fuel is appreciable even for a dwarf star such as the sun. The sun appears to be about 5,000,000,000 years old and to have been shining at its present rate for about 1,000,000,000 years. On the assumption that the sun was initially composed of about  $\frac{4}{5}$  hydrogen by weight, Schwarzschild, Howard and Härm, found that at the present time the concentration of hydrogen in the centre of the sun must be only about 30% by weight. Furthermore, most of the sun was in radiative equilibrium, leaving only about 0.33% in the outer convection zone. In order to maintain its observed luminosity, the sun's central temperature has increased noticeably since the time the solar system was formed, largely as a consequence of the depletion of the hydrogen in the interior with the accompanying increase in molecular weight and temperature. As the sun has evolved it has also become brighter. Schwarzschild, Howard and Härm concluded that over the past 5,000,000,000 years the sun brightened by about half a magnitude, and they suggest that in the early Pre-Cambrian era (about 2,000,000,000 years ago) the solar luminosity was about 20% less than now. The average temperature on the earth's surface must have been about the freezing point of water. It is possible, of course, that the earth's atmosphere might then have acted as a more efficient heat trap and permitted the surface temperature of the earth to be actually higher than this rather cool value.

Table IV, giving results of one calculation of the internal structure of the sun, takes into account both the carbon cycle and the proton-proton reaction. At the centre of the sun the temperature is about 14,600,000° and the density is about 134 times that of

TABLE IV.—Internal Structure of the Sun

$r/R$	Temperature (°A.)	Density (water = 1.0)	$r/R$	Temperature (°A.)	Density (water = 1.0)
0.00	14,600,000	134	0.60	2,500,000	0.405
0.10	12,650,000	85.5	0.70	2,270,000	0.124
0.20	9,350,000	36.4	0.80	1,270,000	0.0354
0.30	6,650,000	12.9	0.90	605,000	0.00945
0.40	4,740,000	4.13	0.96	226,000	0.00217

water. Nevertheless, in spite of its high density the material is very nearly a perfect gas. Weymann's model takes into account the depletion of hydrogen in the interior of the sun, as a consequence of its evolution.

## VII. STELLAR EVOLUTION

From what has been said it is clear that one must anticipate some evolution among the stars. The aforementioned calculations by Schwarzschild and his co-workers of Princeton university show that these evolutionary effects have not been negligible even for the sun. For a more massive star the effects must be even more spectacular since the rate of conversion of mass into energy is increased. The sun produces energy at the rate of about 2 ergs per gram per second, but a luminous main sequence star may produce energy at the rate of 2,000 ergs per gram per second. Consequently, while evolutionary effects may require billions of years to be manifest in a star such as the sun, they may occur within a few millions of years in highly luminous stars. A supergiant star such as Antares, a bright main sequence star such as one of the belt stars of Orion or even a more modest star such as Sirius cannot have endured as long as the sun. Therefore, if it has existed for as long as 5,000,000,000 years it must have spent most of its life as a nonstellar object. Alternatively, these stars may have been formed relatively recently in the history of the galaxy. Thus, one might expect to find within the galaxy (and even within the neigh-

bourhood of the sun itself) stars that are well evolved and/or even approaching extinction, as well as occasional stars that must be very young or even in the process of formation. First, let us examine the life history of a star as it can best be envisaged on the basis of modern theories of physics and stellar evolution. Stars are presumably formed from the grains and gas in the interstellar medium. The material between the stars is not uniformly distributed in space but is spread in a patchy fashion. Occasionally a cloud will form sufficiently massive for gravitational attractions to draw it together.

As it begins to pull itself together, the internal temperature and density start to rise until finally the star breaks into incandescence with a faint red glow. At this stage the star is still shining by its gravitational contraction; i.e., by the conversion of potential energy into heat. As the internal temperatures rise to a few million degrees, deuterium (heavy hydrogen) is first destroyed. Then lithium, beryllium and boron are broken down into helium as their nuclei are bombarded by protons moving at high velocities.

Detailed calculations published by E. Salpeter, by L. Henyey and his associates, and by C. Hayashi show that a star originally falls above the main sequence because it is too bright for its colour. As it contracts it moves downward and to the left toward the main sequence.

Finally, as the central temperature and density continue to rise, a state is reached where the proton-proton or carbon cycle reaction becomes active and the development of the star is stabilized. The star then reaches the main sequence, where it remains for most of its active life. The time required for the contraction phase depends on the mass of the star. A star of the sun's mass may require millions of years to reach the main sequence, while one of much greater mass may reach the main sequence in a few hundred thousand years.

By the time the star reaches the main sequence it is still chemically homogeneous. As time goes on and the hydrogen in the core is converted into helium, the temperature slowly rises to compensate for the depletion of the fuel. If the star is sufficiently massive to have a convective core, the material in this region has a chance to be thoroughly mixed, but the outer region does not mix with the core. In the sun, on the other hand, there is no convective core and the helium-hydrogen ratio is maximum at the centre and decreases outward. During the lifetime of the sun there has been a steady depletion of the hydrogen so that at the centre the concentration of hydrogen is probably only about one third of the original amount. The rest has all been converted to helium.

The rate of evolution depends strongly on the mass of the star. In the sun the effects are only slightly manifest (they could not have been found if observers had not been seeking them). A star of twice the sun's mass burns its energy at such a rate that it cannot last more than about 3,000,000,000 years, whereas a star of ten times the sun's mass has a lifetime measured in tens of millions of years.

As the composition of the star's interior becomes seriously modified it begins to move away from the main sequence, slowly at first, and then more rapidly. When about 10% of the star's mass has been converted into helium, the structure of the star changes drastically. The core becomes inert. That is, all the hydrogen has been burned out and this central region is composed almost entirely of helium with small admixtures of heavier elements. The energy production now takes place in a thin shell where hydrogen is consumed and added to the inert core. The outer portion of the star expands outward, and as the star swells up it may gradually rise in luminosity. The details of the evolution depend on the hydrogen-metal ratio, and the course of evolution will differ for stars of the two population types.

Consider first a globular cluster (fig. 8). The main sequence does not extend to stars brighter than absolute magnitude +3.5. The giant sequence begins at this point and extends on the colour magnitude diagram to the right and vertically upward for several magnitudes. Then it gradually bends over, the most luminous stars in the cluster being the red giants. This colour-magnitude diagram exhibits the effects of stellar evolution. All main sequence stars more massive than about 1.5 solar masses have evolved off

the main sequence and most of them have died. The colour-magnitude array then represents an evolutionary picture of the cluster. The giant branch is not, strictly speaking, the path of evolution but rather the locus or envelope of evolutionary paths. It represents a snapshot of stars of different masses but of the same age. Presumably the stars leave the main sequence and evolve into stars of steadily increasing luminosity until they reach the peak of the diagram. Then what? Presumably later stages of evolution are connected with the horizontal branch at absolute magnitude zero where the RR Lyrae stars and other blue objects are found. The last stages of evolution are represented by the white dwarfs which are too faint to be detected in globular clusters, but they must be present there in great numbers.

F. Hoyle and Schwarzschild have calculated the evolutionary track of a star from the point where it leaves the main sequence until it reaches the top of the giant branch. When the core of the star becomes depleted of hydrogen, the energy generation is confined to a narrow shell and the outer part of the star becomes distended. That is, the star swells up and moves to the right in the colour-magnitude array. The energy is carried outward by large-scale convection currents. By the time about 20% of the total mass of hydrogen has been converted into helium, these convection currents have become so rapid that they approach the velocity of sound. Then as the star evolves upward in the diagram, the temperature in the energy-producing shell begins to rise, slowly at first, then more rapidly until near the top of the giant sequence the central temperature reaches a value of about 40,000,000° K. While this is happening the total energy output of the star rises, and the core shrinks by gravitational contraction. Eventually, it may become a degenerate gas. The compression of the core raises its temperature and density until the core reaches a temperature of about 120,000,000° K. At that temperature, the previously inert helium is quickly consumed in the production of heavier elements. Much of the energy released is expended in speeding up the core electrons and removing the degeneracy of the gas. It never escapes from the star.

If two helium nuclei are jammed together one might expect them to form a nucleus of beryllium of mass 8, thus

Actually  ${}^8\text{Be}$  is unstable and breaks down again quickly into two helium nuclei. If the density and temperature are high enough, however, the ephemeral  ${}^8\text{Be}$  nucleus may capture another helium nucleus to form a nucleus of  $\text{C}^{12}$ , thus

and reactions such as

may also occur. The energy output of helium burning (per ton of material) is much less than for hydrogen burning. The evolution of the star beyond this "helium-flash" stage is highly uncertain. The star presumably moves quickly to the horizontal branch of the colour-magnitude diagram but its lifetime there is not long. Presumably it evolves to bluer colours and lower luminosities but certainly ends as a white dwarf. The energy output of the white dwarfs is so low that they may go on shining by radiating away their store of energy until none is left to emit. The final stage of a star is a ball not much larger than the earth, but with a density 50,000 times that of water, possibly covered with a thin layer of ice and surrounded by an atmosphere of hydrogen and helium a few feet thick.

One of the interesting results of the calculations by Hoyle, A. R. Sandage and Schwarzschild is a determination of the ages of globular clusters. The critical datum is the point in the colour magnitude diagram at which the main sequence ends. In some globular clusters it appears that this point falls below a solar mass. Such objects are presumably ten thousand million years old or older. The results are strongly influenced by observational uncertainties. Certainly, the globular clusters are very ancient

FIG. 9.—COLOUR-MAGNITUDE ARRAYS FOR FOUR GALACTIC CLUSTERS OF DIFFERENT AGES

objects, probably among the oldest in our galactic system.

Turning to population type I a very different situation is found. If the colour-magnitude arrays for different galactic clusters are compared, the situation is that exhibited in fig. 9. In the double cluster h and  $\chi$  Persei the main sequence extends to about magnitude -6 where it turns off abruptly to the right. There are also a few red supergiant stars. The Pleiades main sequence turns upward from the usual main sequence at about magnitude 0 but there are no giant stars while the Praesepe (Beehive cluster in Cancer) shows a giant sequence and a main sequence that is curved up at about +2. The cluster M67 has a colour-magnitude array that resembles superficially that of the giant branch of a globular cluster, except that there is no horizontal branch and the most luminous giants are much fainter than the globular cluster giants.

The feature distinguishing these different clusters is their different ages. The youngest cluster, the pair h and  $\chi$  Persei, contains stars of a great range in luminosity. Some stars have already evolved into the supergiant stage so that the top end of the main sequence is bent over. The stars of luminosity greater than 10,000 times that of the sun have already largely depleted the hydrogen in their cores and are leaving the main sequence.

The brightest stars of the Pleiades (Alcyone, Maia, Taygeta, etc.) have started to leave the main sequence and are approaching the critical phase when they will have exhausted all the hydrogen in their cores. There are no giants in the Pleiades. Presumably the cluster contained no stars as massive as some of those found in h and  $\chi$  Persei. The cluster is also older than the double cluster.

The Beehive or Praesepe cluster is still older than the Pleiades. All stars much more luminous than Procyon (+3) have started to leave the main sequence, and there are some giants. The Hyades display a similar colour-magnitude array. These clusters contain a number of white dwarfs, indicating that the initially most luminous stars have already run the full gamut of evolution. Finally, M67 must be the oldest cluster of all; the best data of stellar structure indicate that it is several thousand million years old. All the bright main sequence stars have long since disappeared.

Some estimated ages of typical galactic clusters, judged from

TABLE V.—Estimated Ages of Typical Galactic Clusters

Cluster	Age (millions of years)	Cluster	Age (millions of years)
Orion association	<1	Praesepe	320
h and $\chi$ Persei	12	Hyades	700
Pleiades	50	M67	5,000

Source: After Sandage (1958), Lohmann (1957), and Von Hoerner (1957).

the turnoff points of the main sequence, are given in Table V.

Hoyle and Schwarzschild were also able to establish that the difference between the giant branches in M67 and in the globular clusters was to be attributed to differences in chemical composition, in particular to the hydrogen-metal ratio. In the type II stars, they took the ratio of hydrogen to the metals by numbers as 135,000 (in accordance with the spectroscopic data for the subdwarfs) whereas for the type I stars they took a ratio of 10,000. The population type I giant stars, as a consequence of their larger metal contents, produced a more extended envelope and hence later spectral classes.

The giant stars of the Praesepe are comparable with the brightest stars in M67. Now the M67 giants have evolved from the main sequence near absolute magnitude +3.5, whereas the Praesepe giants must have evolved from main sequence stars of absolute magnitude about +0.5. Consequently, the Praesepe giants must have masses about twice as great as those of the M67 giants. Thus the failure of the mass-luminosity law for giant stars is easily understood. Giant stars of the same luminosity may therefore have appreciably different masses.

An example in point is provided by the components of the giant star Capella, for which K. O. Wright found masses three times that of the sun, whereas each component of the giant binary TW Cancri has a mass 1.3 times that of the sun, according to D. M. Popper. Thus Capella is presumably a relatively young star, TW Cancri an ancient one.

Several other differences between the various galactic clusters are to be noted. The M67 giant sequence is continuous with the main sequence, whereas there is an appreciable gap between the giant and main sequence stars in the Praesepe and a much wider one in h and  $\chi$  Persei. One suspects that these vacant regions are connected with domains of instability in the structure of the star.

One interesting fact noted by R. Kraft and John Irwin was that several Cepheids are found in galactic clusters, and in each instance where the colour-magnitude arrays can be constructed the Cepheid appears to fall in the gap.

If some star clusters such as h and  $\chi$  Persei are only a few million years old, whereas others such as the Hyades are a thousand million years old, the process of star formation in clusters must be going on at the present time, and we ought to be able to catch occasional stars or groups of stars in the process of formation. G. Herbig and G. Haro have found evidence that the T Tauri stars, variables found only in regions where there are great quantities of interstellar dust and gas, are stars in the process of formation. They probably are still contracting and have not yet started to shine by thermonuclear hydrogen burning reactions.

Some of the most striking evidence for star formation was found by Parenago in the region of the Orion nebula and by M. F. Walker in the cluster associated with S Monocerotis NGC 2264.

## VIII. FORMATION OF THE ELEMENTS IN STARS

Many years ago in an anonymous communication to a scientific journal William Prout proposed the hypothesis that all elements originated from hydrogen. Although this suggestion gathered dust for many years it has been revived in connection with the possible origin of elements within stars. Astronomers and nuclear physicists have devoted much effort to this problem.

The first investigation of the abundances of elements was undertaken by F. W. Clarke and H. S. Washington, who analyzed samples of the earth's crust. Later, V. M. Goldschmidt pointed out that a much more representative sample of the probable composition of our part of the universe could be obtained from meteorites, at least as far as nonvolatile constituents were concerned. Finally, in his

pioneering analysis of the sun, Russell gave the first clear perspective of the relative abundances of the elements in our part of the universe. Subsequent work has revised and extended Russell's early results; in particular, it has demonstrated the overwhelming preponderance of hydrogen and helium, compared with which all other elements can be regarded as mere impurities. Table VI, based largely on work at the University of Michigan on the composition of the sun and early-type stars, gives the most abundant elements (by numbers) in a representative sample of our part of the universe.

Among the elements lighter than iron which have even atomic numbers, those with atomic numbers divisible by four tend to be most abundant (rule of Oddo and Harkins). Other abundance effects have been noted; the abundances of light elements tend to be greater than those of heavier elements. That is, a plot of abundance against atomic weight,  $A$ , shows a decline with increasing  $A$  to about  $A = 100$ . Thereafter the abundance is more nearly constant. A plot of numbers of atoms against atomic weight or number is far from smooth. Aside from the irregularities produced by the rule of Oddo and Harkins there are huge fluctuations for certain elements. Thus lithium, beryllium and boron are very rare compared with carbon, nitrogen or oxygen. There is a pronounced abundance peak at iron and less conspicuous peaks at other elements, often connected with the so-called magic number nuclei. There is also a maximum at lead, the most stable of heavy elements.

TABLE VI.—The Most Abundant Elements (by Numbers)  
(Silicon = 10,000)

Element	Abundance	Element	Abundance
H	$3.2 \times 10^4$	P	79
He	$5.1 \times 10^4$	S	7,100
C	125,000	Cl	550
N	35,000	Ar	2,400
O	280,000	Ca	16
F	300	Sc	470
Ne	141,000	Ti	17
Na	89	Cr	52
Mg	8,000	Mn	30
Al	525	Fe	1,250
Si	10,000	Ni	280

Astronomers and physicists believe that the abundance curve of the elements provides definite clues as to their origins. The preponderance of hydrogen suggests that perhaps all nuclei were built up from protons. G. Gamow suggested that the elements were created as the consequence of the expansion of a huge mass consisting of neutrons. As the density decreased the neutrons decayed into protons and electrons. The protons then captured neutrons, one after another, underwent beta decay (ejection of electrons) and built up heavy elements. The big difficulty with this hypothesis is that atomic masses 5 and 8 are unstable and there is no way to build nuclei beyond helium. Other difficulties have been pointed out, and the Gamow hypothesis must be greatly modified or discarded.

The alternative hypothesis to the effect that heavy elements are built in stars has much to recommend it. Consider, first of all, the following observation facts. Not all stars have the same chemical composition. A long time ago R. H. Curtiss pointed out that the splitting in the spectral sequence among the cooler stars could be understood in terms of composition differences. The R and N stars contain more carbon than oxygen, whereas the S stars appear to have an enhanced content of zirconium as compared with titanium. From a more detailed spectroscopic study of the cool stars, P. W. Merrill has found evidence for differences in both the carbon-oxygen ratios and in the ratio of the zirconium group to titanium group of metals. The M stars appear to have a "normal" (i.e. Solar) composition with oxygen more abundant than carbon and the zirconium group of elements much less abundant than the titanium group.

Other abundance anomalies are found in the Wolf-Rayet stars where objects containing predominantly helium, carbon and oxygen are distinguished from objects containing helium and nitrogen, some carbon and small quantities of oxygen.

Significantly, all these abundance anomalies are found in stars believed to be well advanced in their evolutionary development.

No main sequence dwarf stars show such effects.

The most critical observation, however, was Merrill's detection of the unstable element technetium in the S stars. The element has been produced on the earth synthetically. The longest lived isotope  $\text{Tc}_{43}^{99}$ , which can be produced by neutron capture, has a half life of 200,000 years and can be formed by the following reaction:

That is, molybdenum of mass 98 captures a neutron to form molybdenum of mass 99, which decays (in about 67 hours) to form technetium of mass 99 with the ejection of a negative electron. Furthermore, the Tc in the S stars appears to be about as abundant as the neighbouring elements, ruthenium and molybdenum. The implication is that all these elements were built in the S stars and that these objects have lifetimes of about 200,000 years. How the star gets the heavy elements from the core to the surface without exploding is unknown at present.

Work by the Burbidges, F. Hoyle, W. Fowler and A. G. W. Cameron has demonstrated how elements may be built in stars by nuclear processes occurring at very high temperatures and densities. No one mechanism can account for all the elements, and several distinct processes have been proposed.

The great abundance of helium is easily understood. It is the normal "ash" of hydrogen consumption. In the dense cores of massive stars the helium itself may be consumed to form  $\text{C}^{12}$ ,  $\text{O}^{16}$ ,  $\text{Ne}^{20}$  and  $\text{Mg}^{24}$ . At yet higher temperatures a host of nuclear reactions may occur to produce the elements up to iron. Heavy elements such as zirconium cannot be produced in this manner. Apparently, the only way they can be formed is by the capture of neutrons.

Cameron suggested that the light isotope of carbon,  $\text{C}^{13}$ , could get mixed into the helium core and combine with alpha particles (helium nuclei) to produce  $\text{O}^{16}$  and neutrons in accordance with the following reaction:

These neutrons are available for capture by heavier nuclei, particularly those with large target areas, to form yet heavier elements. Thus the elements of the zirconium group, for example, could be built from lighter elements by successive neutron capture. Fowler and the Burbidges suggested other nuclear processes that could result in the production of neutrons and the subsequent formation of heavy elements. They concluded that about 40% of the iron in a mixture will be transformed into heavier elements if about 20 neutrons could be produced for every iron atom in the mixture.

After a given nucleus captures a neutron, it may find itself too heavy for its charge and decay into the nucleus of the element next to it in atomic number. Beta decay is often very slow, and if the flux of neutrons is high the nucleus may capture another neutron before it can undergo decay. Hoyle suggested that in supernovae explosions vast quantities of neutrons are produced and these result in the rapid build-up of massive elements. One interesting feature of the building up of heavy elements by neutron capture at a high rate in a supernova explosion is that nuclei much heavier than lead or uranium can be built. In particular, nuclei of the synthetic element californium 254 may be produced; these nuclei decay by spontaneous fission with a half life of 55 days.

Hoyle, the Burbidges and Fowler suggest that the vast supplies of energy liberated in supernovae outbursts may be connected with this reaction since the light curve of a supernova closely resembles the decay curve of  $\text{Cf}^{254}$ . In any event it is not possible to explain all the different kinds of isotopes of all the elements with their proper abundance ratios without invoking several different mechanisms.

Thus helium clearly comes from hydrogen burning; carbon, oxygen, neon and magnesium come from the subsequent consumption of helium in three particle reactions.

The abundance peak at iron is presumed to be produced by an equilibrium between various types of nuclei set up at enormously

high temperatures and densities—possibly in supernovae.

Some nuclei must be produced by neutron captures that proceed at a leisurely rate. Thus, whatever produces the neutrons in the cores of the S stars does so in such a way that the neutrons are captured by nuclei at such a rate that these new nuclei may undergo beta decay (ejection of positive or negative electrons) before a new neutron is captured. Other nuclei must be produced by the rapid capture of neutrons by nuclei in such a way that beta decay cannot occur before another neutron is captured.

No known nuclear process is capable of producing deuterium (heavy hydrogen), lithium, beryllium and boron in stellar interiors. They are probably produced by the breaking down of heavier elements, such as iron and magnesium, by high energy particles in stellar atmospheres or in the early stages of stellar formation. Presumably these high energy particles originate as a consequence of electromagnetic disturbances in the neighbourhood of sunspots and are probably connected with such things as flares, which may be more active in early stages of a star's gravitational contraction to form a stable body.

Finally, in certain of the magnetic stars, some elements such as the rare earths have enormously enhanced abundances. Possibly the nuclei of these elements also are produced by high energy reactions involving electromagnetic accelerations of charged particles.

Nuclear astrophysics is a new field, but it promises to be one of the most exciting aspects of stellar astronomy. The connections between stellar evolution, stellar composition differences and element building appear to be dimly perceived and should provide an enduring impetus to future research. **STARACHOWICE**, an industrial town in Kielce województwo (province), Poland, on the railway between Skarżysko Kamienna and Sandomierz. Pop. (1960) 36,000. It lies on the Kamienna River, a tributary of the Vistula, in the Little Polish Highlands. Known as a mining centre from the 16th century, its development dates from the establishment in 1789 of iron foundries; between the two world wars they were among the largest in Poland. Starachowice is now a centre of the mining of iron ore and of the metal industry. The factory for lorries (trucks) and buses was established there after World War II.

(T. K. W.)  
**STARAYA RUSSA**, a town of Novgorodskaya Oblast' of the Russian Soviet Federated Socialist Republic, U.S.S.R., stands on the Polist' River, where it is crossed by the Pskov-Bologoye railway, 12 mi. (19 km.) S of Lake Ilmen. Pop. (1959) 25,409. The town is first mentioned in 1167, when it was an important centre of Novgorod's territories. A stone cathedral was built in 1198 and a kremlin in 1199. Salt was worked nearby. The town is now a minor local centre, with brick making, tanning, and timber working. There is a spa based on local salt springs and mud.

(R. A. F.)  
**STARA ZAGORA**, a town and centre of Stara Zagora okrug (district), situated in the southern foothills of the Sredna Gora Mountains and on the fringe of the Stara Zagora plain in south-central Bulgaria. Pop. (1961 est.) 75,523. The town is on the Plovdiv-Burgas railway and has an airport. It is an educational centre and has a museum and a broadcasting station. The modern Stara Zagora spa lies 9 mi. (14 km.) NW of the town. Industries include the initial processing of cotton, the manufacture of cotton textiles, chemical fertilizer, agricultural tools, furniture, and cigarettes, and brewing and canning. There is a hydroelectric power station nearby and many vineyards in and around the town.

In Roman times there was an important fortress at this site, known as Augusta Trajana; in Byzantine times it was called Beroea, in the Middle Ages Borui. The Turks built a fortress in

the 15th century known as Eski-Zagra, around which grew up a farming, craft, and trade centre. During the Russo-Turkish War of 1877-78 the town was destroyed. After the liberation it was restored, and in the 1950s and 1960s was rebuilt. (L. Dr.)

**STARCH** is a complex carbohydrate that occurs, often in great abundance, in almost every living plant. It serves as the plant's reserve food supply through dormant periods and in plant seeds as a source of carbohydrate until the seedling can become self-supporting. It is stored in much the same manner that carbohydrate (dextrose) is stored as glycogen by higher animals.

Starch is the major constituent of the average diet and one of man's principal sources of energy. Its many commercial uses include food processing, laundering preparations, and the manufacture of items such as paper, textiles, adhesives, explosives, and cosmetics.

**Occurrence and General Properties.**—Although its exact structure is unknown, starch has the approximate formula  $(C_6H_{10}O_5)_n$ . It belongs to the group of carbohydrates known as polysaccharides; that is, it is a high polymer composed of sugar units. In starch these sugar units, or chemical building blocks, are all dextrose, as is the case with a related polysaccharide, cellulose.

Starch is found in transitory form in green leaves, where its chemical synthesis is begun. For transfer to more permanent storage areas it is broken down into sugars that dissolve in the cell juice, in this way passing through the cell walls of the plant, finally to be reconverted into starch in roots and tubers, or in stems (such as the pith of palms), or in fruits and seeds. In many cases, such as in corn grain, starch may constitute as much as two-thirds of the total dry weight of the seed. Some tubers, such as the white potato, contain more than 90% starch, dry basis, but, because of the high water content, the actual starch content is only about 15-30%.

Starch occurs as tiny white granules that are insoluble in cold water and are remarkably resistant to bacteria and molds. The size, shape, and other superficial characteristics of starch granules vary considerably, depending on the source. It is therefore possible to determine microscopically whether the starch has been obtained, for example, from corn grain, potatoes, or arrowroot.

**Early Uses.**—Discoveries of manufactured articles, such as papyrus paper from ancient Egypt (about 3500 B.C.), indicate that starch was used as a size or adhesive. The Greek name for starch, *amylon*, suggests that ancient peoples prepared starch "without milling," i.e., not by the dry-milling procedures used to make flour from cereal grains, but by soaking cereal grains, such as barley or wheat, under water until soft and then pounding them in a mortarlike device to produce a suspension of starch granules in water. The "starch milk" was drawn off, sieved through fine cloth, allowed to settle, and the water then decanted, leaving a sediment of rather pure starch, which was spread out to dry.

Though starch was easily obtained in fairly pure form, no extensive industry was established to produce it until modern times. Even as late as the 17th and 18th centuries, one of the principal uses for starch appears to have been to powder wigs, with an additional small amount used to stiffen certain articles of clothing. However, with the Industrial Revolution in the 19th century, increasing applications for starch were found in the manufacture of textiles, paper, food, and other products. Many further uses were made possible by the discovery of G. S. C. Kirchhoff in 1811 that when starch is heated in a dilute acid solution it is broken down (by hydrolysis) into a sweet sirup containing the sugar dextrose (frequently called glucose).

**Manufacture.**—Modern starch manufacture uses the same basic processes as those used by the ancients, i.e., wet-milling processes. Variations occur with the different substrates, whether they are, e.g., cereal grains, roots, tubers, or stem pith. Industrial processes are limited to only those sources that can be grown economically in abundance. Of these the most important are corn (maize), tapioca (cassava, manihot, manioc, yucca), white and sweet potatoes, rice, wheat, and sago. Corn is used largely in

the Western Hemisphere and to some extent in Great Britain and Europe. Tapioca starch is made principally in the East Indies and in South America. Europe has been the chief producer of white potato starch, whereas sweet potatoes and rice starches are produced in considerable volume in the Orient. Small amounts of wheat starch are made in scattered localities in both the Eastern and Western hemispheres. Some sago starch is produced in the East Indies, and arrowroot starch is made almost exclusively in the British West Indies.

The type of starch used for a specific purpose depends on its cost, purity, the stiffness or viscosity of the paste it makes with hot water, and the size of the granules. Potato, corn, rice, and wheat starches are those chiefly used for industrial purposes; rice, corn, arrowroot, cassava, and sago for foodstuffs; and the small-granuled starches, rice and corn, are used extensively for laundering since the granules are required to enter the texture of the cloth before becoming gelatinized by the hot iron.

**Wet-milling Processes.**—When starch is heated with water it forms a paste, the physical characteristics of which are different for each type of starch. Aside from the differences in these pastes due to the variety of starch grains, the properties are further modified by mechanical and chemical action. When starch is heated in plain water, it takes on water and hydrates; the granular packages first swell and then rupture to form a paste. The body and consistency of the pastes vary greatly, depending on the severity and intensity of the cooking and agitating treatments. These modifications are due mainly to mechanical means—that is, the granules are merely torn without materially altering the chemical structure. In the presence of chemicals, however, particularly acids and enzymes, the molecule itself is degenerated, the products formed representing a breakdown of the original molecule. The type of starch degeneration product formed in the presence of these chemicals and the extent to which the original molecules are degenerated will depend on the nature of the chemical substance, concentration, temperature, etc. In this manner are made the thin-boiling (low-viscosity) starches, dextrans, sirups, and sugars. This process is employed in the manufacture of corn or glucose sirups, used extensively in confectionery, and of glucose sugar used in brewing. Hydrolytic degeneration is also effected by certain natural ferments or "enzymes" such as those in saliva, pancreatic juice, and malted grain (diastase); it is the last agent that is employed in fermentation industries such as brewing, distilling, etc., to convert starch into material capable of fermentation by yeast.

Dry starch heated to upwards of 320° F (160° C) is transformed into dextrin, a pale yellowish powder soluble in water, known as British gum. Dextrans of lighter colour are also made by spraying with aqueous acids and heating to lower temperatures.

The general principles for dealing with all types of roots and tubers are substantially the same but vary in their elaboration and efficiency in different parts of the world, and they also differ to some extent in detail when cereals are treated.

The tubers first go through washing machines where earth, stones, sand, and grit are removed; they then pass to a rasping machine where all the cells are completely ruptured. The resulting pulp is washed in a fine stream of water on fine-mesh brass sieves that separate the starch from vegetable fibre, etc.; the resulting milky starch liquor is run into vats to separate fine sand and grit by settlement, through fine silk sieves for further purification, and finally over long, shallow, wood troughs, runs, or tables, where the pure starch settles out and the impurities pass off at the ends with the water. The pure white starch is washed from the runs by a jet of water and is pumped to either filter presses or centrifuges, which remove all except about 40-45% of the water, leaving the starch in the form of a damp cake.

The cereals contain varying proportions of protein or gluten material associated with the starch, and special methods are employed in their preliminary treatment. The protein contained in rice is found to be rendered soluble by very weak caustic soda solution, and advantage is taken of this in the production of starch from the raw material. For corn it is necessary further to remove the corn germs, which contain large amounts of corn oil.

In this case the grain is first steeped for about two days in warm, dilute sulfurous acid (about 2%). The grain is then roughly ground, and the separated hull is removed from the ground mass by coarse screens. The corn germs are floated away from the remaining major components, namely, starch, corn gluten, and corn-grain fibre. These components are passed to mills where they are reduced to very fine particles. Residual fibre is removed by very fine screens, and the resulting suspension of starch in water is separated from the corn gluten by centrifuges. (The gluten, after partial dehydration and drying, is used for food or adhesives.) After a further washing, the starch is de-watered by centrifuges or filters until a wet cake remains.

Wheat contains gluten which forms an elastic paste with water and cannot be removed by levigation (separation of coarse from fine particles in a suspension). The procedure carried out in this case is to reduce the grain to flour, which is then made into a dough with water, divided into small pieces, and placed in a semicircular silk or fine brass sieve where a traveling roller presses out the starch, which is then removed by a fine spray of water. The starch liquor goes through a similar purification process to that employed for corn, often being treated with dilute caustic soda solution to swell the gluten and assist its removal between the sieving processes.

**Drying.**—The final drying process must be carried out at very low temperatures to prevent the gelatinization of the starch granules. Several methods, similar in principle for starches from all sources, are in use in the large factories and consist of either bringing the starch lumps or blocks in contact with a continuous current of warm air or evaporating off the excess moisture in a vacuum chamber. For producing the starch in the form of powder or flour the moist lumps are either placed on an endless band running backward and forward in an enclosed chamber through which warm air is drawn, or they are placed on trays mounted on a trolley and passed through a tunnel in contact with warm air. For food uses and other applications, the dried starch is ground and passed over very fine silk sieves, or air classifiers, to produce a fine powder.

Prism or crystal starch, prepared from corn or rice starch for laundry purposes, is produced by forming the damp starch into blocks by draining off the water from the starch liquor in boxes with perforated bottoms covered with filtering cloths; the blocks are cut into two or more sections and are partly dried in a warm chamber; the yellowish-brown crust that forms on the outside is scraped off, and the blocks are wrapped in paper, returned to the drying chamber, and dried very slowly. Under this treatment the blocks break up into irregularly shaped prisms technically termed "crystals." Pearl tapioca is made by heating the slightly moist starch from manioc in a steam-heated copper pan with constant stirring, some of the cells becoming gelatinized and adhering together in small, irregular masses. After further drying the crude lumps are passed through rollers and graded.

Granulated or pearl sago is prepared by drying the starch in such a way that it forms a plastic dough in which a portion of the granules have become gelatinized, forcing this through sieves, and drying the resulting granules in the air.

**Industrial Applications.**—One of the largest industrial uses for starch is as a size in paper manufacturing. It increases the paper's strength, reduces porosity, and provides a better printing or writing surface. Corn sirups, used largely as food sweeteners, are also important in the textile, leather tanning, adhesive, pharmaceutical, paper, and tobacco industries. Aside from its use as a sweetening agent, starch itself is used in the food processing industries as a thickening, emulsifying, or gelling agent. In the textile industries a thin-boiling grade is employed to size yarns for protection during weaving operations. Other grades of starch, as well as dextrins, are used to size-finish various woven fabrics. Starch and dextrins are used as adhesives, particularly in the paper- and paperboard-converting industries, in making bags and boxes. Besides being important source materials for the fermentation industries, starch and starch products have such varied uses as a drilling-mud conditioning agent for drilling oil wells, as a coagulant in refining aluminum ore digests, as a

binder in the production of sand molds in foundries and in printing paste, and as a vehicle for dyes in printing calicoes and acetates.

**STAR CHAMBER** was the name given, because of the stars depicted on the ceiling of the main room, to a building in the king of England's palace of Westminster. It was constructed in the reign of Edward III and apparently from the first was one of the regular meeting places of the king's council. In the 16th century the name came to be applied also to the meetings there of councilors and judges sitting as a court.

This court inherited its jurisdiction from the medieval king's council (see **PRIVY COUNCIL**). The king of England, despite the evolution of the various courts of common law from the 12th century onward, had never parted with supreme jurisdiction or the right to supplement and reinforce the action of the ordinary courts. This right he exercised largely through his council, which dealt also with judicial business that fell outside the normal scope of those courts. Thus, to the council were referred, from at least the early 14th century, the petitions of suitors who sought the special intervention of the crown either because the ordinary courts had no remedy to offer in their cases or because the remedies were being frustrated by force or fraud or corruption. The council as a body did not itself deal with all these matters. Cases directly involving life or property were regarded as outside its scope and were generally left to the common-law courts. Many petitions, too, were about private matters between subject and subject, civil causes in which the crown's interests were not directly involved.

The council, while retaining undisputed control over all complaints addressed to it, fell into the habit of referring more and more of these cases of little public concern, and often great legal complication (e.g., trusts and uses, or breach of oral contract), to the chancellor and a few other councilors and then, from the later 15th century, to the chancellor sitting alone. A similar course was adopted, rather more erratically, with the growing number of petitions from poor men and royal servants. Richard II gave the lord privy seal some special responsibility for these and by Richard III's time certain councilors were acting as "masters of requests"—perhaps as a "court" of requests—to deal with them.

The council as a body, however, generally retained for its own peculiar province the handling of cases involving public order, such as riot, breach of the peace, the maintenance of lawbreakers, the keeping of retainers and the corruption of officials in which the crown had a more direct interest. Here its procedures gave it considerable advantages over the ordinary courts. It was less bound by rigid forms. It did not depend upon juries either for indictment or for verdict. It could act upon the petition of an individual complainant or upon information received. It could put an accused person on oath to answer the petitioner's bill and to reply to detailed interrogatories. It had the help of the judges in reaching its decisions and its sentences were backed by the full majesty of the state and the law. On the other hand its methods lacked the safeguards which common-law procedures provided for the liberty of the subject, and parliaments in the 14th and 15th centuries, while recognizing the occasional need for and usefulness of those methods, had attempted to limit their use to causes beyond the scope or power of the ordinary courts. Thus the judicial activity of the king's council in these matters continued to be in the nature of a special intervention from outside the regular course of justice.

Under the Tudors, however, this activity became so frequent and continuous that it developed into a regular part of the normal machinery for enforcing the law. Henry VII (q.v.), having a council fully obedient to the royal will, made great use of its jurisdiction to repress lawlessness, particularly riot, livery, maintenance.

embracery and corruption of sheriffs and jurors. His famous act of 1487, later misleadingly titled *pro camera stellata*, though it did not create a court of star chamber, did reassert statutory sanction for regular employment of the council's procedures in such cases as those just mentioned. Also, using a common Tudor device, it placed upon certain councilors a special responsibility for dealing with them. Moreover, the councilors named included the lord chancellor and the two chief justices (or two other judges) of the courts of king's bench and common pleas. As these were all tied to Westminster during term time, the act confirmed the council's habit of dealing with such cases in term time at its headquarters, the star chamber. For it did not, of course, prevent other councilors, if available, from dealing with those causes, nor did it in any way limit the meetings in the star chamber to these matters or indeed to judicial business. Nevertheless, the presence of the judges helped to distinguish these meetings from others; and in general the act helped to give greater fixity of place and greater regularity of time to this aspect of the council's judicial activity.

It was during Thomas Wolsey's chancellorship (1515-29) that this activity, as well as the activity of chancery in civil equity (see *ENGLISH LAW: The Growth of Equity*), grew with greatest rapidity. He not only used it, with as much vigour as Henry VII, against riot, maintenance and so forth; he also used it with increased vigour against perjury, forgery, fraud, slander and any actions that could be considered as tending to breach of the peace. And he encouraged suitors to appeal to it in the first instance and not merely after failing to find an efficient remedy in the ordinary courts. Thus, with Wolsey this activity of the king's council began to take its place as a regular part of the administration of justice, as a regular "court" alongside the ordinary courts of law. At the same time, the continued growth and increasing definition of chancery's equity jurisdiction in civil suits between subject and subject; the final emergence of a distinct court of requests for poor men's causes; and such other developments as that of the high court of admiralty—all helped to define, as it were by subtraction, the function of the meetings of councilors and judges in public session in the star chamber. They became meetings, above all, for the exercise of the semicriminal jurisdiction of the king-in-council. Not exclusively so, for "all cases may be here examined and punished if the King will"; but matters of riot or tending to riot, robbery, libel, slander, perjury and offenses against royal proclamations were their primary concern.

The final stage in the evolution of this semicriminal jurisdiction of the king's council into the court of star chamber came with the emergence of a more clearly defined privy council. This was, again, the result of pressure of business, this time of executive and administrative business following upon the breach with Rome. The privy council, while retaining and frequently exercising (under the name of the council table) a "supereminent" jurisdiction, was evolved primarily to perform the advisory and executive functions of the older king's council. It attended upon the king; it met in private, all the year around, and often daily. In 1540 it began to have its records kept in a separate book by a clerk (later four clerks) of its own, distinct from the senior clerk of the council (who came to be called clerk of the star chamber). From that date its activities can thus be fairly clearly differentiated from the public sessions of councilors and judges held in the star chamber at Westminster, as a rule during term time only, and usually (at least by the time of Elizabeth I) on Wednesdays and Fridays. These meetings then gradually ceased to be thought of as meetings of the king's council and came to be regarded as sessions of a court of star chamber.

Even so, the distinction between this court and the privy council remained one of function and procedure rather than of persons. Certainly under Elizabeth I and the Stuarts membership of the court was, except for the presence of the judges, almost entirely confined to privy councilors. As a result, it retained much of the majesty, even if it lost the name, of the king's council. It also, of course, continued to use the conciliar procedures. Cases began upon petition or information. The accused, summoned by

writ of subpoena, had to answer on oath and could be examined upon interrogatories framed by the prosecution. Depositions were taken from witnesses, but no jury was used. Proceedings were in English and much was done in writing. The punishments, which were arbitrary and sometimes made to fit the crime, included imprisonment, fine, the pillory, whipping, branding, mutilation, but never death.

The court did useful work in enforcing the law where other courts were subject to corruption or perversion, in providing remedies where others were inadequate, and in supplementing local justice. Its popularity in the 16th century was great—it has been estimated that about 43,000 cases may have come before it during the reign of Elizabeth I. That popularity lasted well into the Stuart period, despite the court's increasing fees and the growing number of its officials. Sir Edward Coke, for example, described it as "the most honorable court (our parliament excepted) that is in the Christian world." However, its employment to enforce unpopular policies, particularly in ecclesiastical matters, made it increasingly hated by the parliamentary and Puritan opponents of Charles I and of Archbishop Laud. As a result it was abolished by an act of the Long parliament in 1641.

(R. B. WM.)

**STAR CLUSTER.** In the astronomical sense, a star cluster is a stellar organization held together by the mutual gravitational attraction of its members, which are physically related through common origin. They move through space together like a swarm of bees. Binary and multiple stars, star clusters and star clouds are all examples of gravitational organizations of generically related stars. Star clusters are distinguished from star clouds by their subordinate size. In some instances, clusters appear as condensations or subsidiary organizations within star clouds.

On the basis of definition, there is no strict separation of multiple stars and very poor star clusters. The astronomer employs the descriptive term that is most convenient. As a working rule, a star cluster should contain enough stars to be describable statistically.

Related to star clusters are stellar associations, loose space groupings of stars of common origin without sufficient total mass in the group to remain together as an organization. In some cases, star clusters or multiple stars appear as nuclei within associations. The expansion rates of some associations have been measured. Associations are, in terms of the usual astronomical time scale, disintegrating rapidly. The stars composing them must have been formed comparatively recently. The measured rate of expansion of the  $\zeta$  Persei association, for example, indicates that the stars composing the association must have been formed approximately 1,300,000 years ago.

**Classes of Star Clusters.**—In the galaxy, the huge stellar system of which the solar system is a member of insignificant size, two general classes of star clusters are found: globular clusters and galactic clusters. These two classes of objects may be briefly contrasted as follows: The globular clusters contain very large numbers—tens or hundreds of thousands—of stars. The galactic clusters typically contain rather few stars—only a few tens or hundreds. The brightest stars in a typical globular cluster are red. They are distended stars of low surface temperature. Generally, the brightest stars in a galactic star cluster are blue.

These two kinds of clusters, which differ so markedly in their physical properties, are found in characteristically different parts of the galaxy. Fig. 1 shows a schematic side view of the galaxy, with its in excess of 100,000,000,000 stars. It is primarily a flat system, roughly circular in plane view, with a diameter of the order of 100,000 light-years. Spiral arms, similar to those seen in many external galaxies, marked out by highly luminous blue stars, gas and dark, nonluminous material, exist in this plane. The galaxy is rotating around an axis perpendicular to the flat plane and passing through the centre, or nucleus, of the galaxy. At the sun's position, about 30,000 light-years from the galactic nucleus, approximately 200,000,000 years are required to complete one rotation. The galaxy does not rotate as a solid disk.

Shorter or longer rotation periods are observed for objects nearer to, or more distant from, the centre.

The galactic star clusters are found primarily in the galactic plane and there predominantly within the spiral arms. As judged by the kinds of stars they contain, as well as by their motions

FIG. 1.—SPACE DISTRIBUTION OF GALACTIC AND GLOBULAR STAR CLUSTERS

Our stellar system as it would appear to an outside observer. Dotted line indicates probable outline of flattened lens-shaped system formed by the stars, as seen edgewise. Eccentric position of our sun is shown by cross. Known galactic star clusters are scattered among the stars in shaded region. Small circles represent globular clusters surrounding the star system like satellites

and space distribution, the galactic clusters are related to the Milky Way star clouds. They, like the star clouds and other objects associated with the spiral arms, must have originated in the highly flattened outer parts of the stellar system. They move in orbits that are approximately circles centred on the galactic nucleus and lying in planes close to and nearly parallel to the galactic plane.

The globular star clusters, of which more than a hundred are now known to be members of the galactic system, differ markedly from the galactic star clusters in their distribution in space. The globular clusters are distributed in the form of an extensive halo about the galaxy (see fig. 1). They have their greatest space concentration in the region of the galactic nucleus and are probably generically related to the stars in the nucleus and the galactic halo. As a system, they rotate about the axis through the galactic centre, but much more slowly than the stars forming the main body of the galaxy. Individual globular clusters move around the galactic nucleus in greatly elongated orbits that lie in planes of various orientations.

**Lists and Catalogues of Clusters.**—Many of the most outstanding examples of star clusters of both classes were discovered by the early telescopic observers of the 17th and 18th centuries. In 1874 the French astronomer Charles Messier published a catalogue of nebulae and clusters in which he tabulated 57 star clusters. A systematic search of the whole heavens undertaken by Sir William Herschel and continued by his son Sir John Herschel led to the discovery of the majority of clusters known at present. The cluster catalogue published by Alter, Ruprecht and Vanysek (1958) listed 117 globular clusters and 576 galactic clusters.

Whenever possible, a cluster is designated by its number in the *New General Catalogue of Nebulae and Clusters of Stars* (N.G.C.), or *Index Catalogues* (I.C.), compiled by John L. E. Dreyer. Less frequently, it is designated by its number in the catalogue published by Messier, or its name, such as the Pleiades, if it is a well-known cluster.

Clusters exist in external galaxies, as well as in our own. This discussion will be limited to members of our own galaxy.

## GLOBULAR STAR CLUSTERS

**Total Number in the Galaxy.**—The halolike distribution of globular clusters about the galaxy causes many of them to appear at high galactic latitudes, well away from the great masses of stars and dark clouds of obscuring material that form the body of the galaxy. The dense globular clusters are thus seen against a sparse stellar background and are readily discovered. Their great intrinsic brightness (10,000 to 1,000,000 times the sun's luminosity) makes them visible even at great distances. The list of known globular clusters that belong to the galactic system must therefore be at least 50% complete.

**Classification of Globular Clusters.**—By Appearance.—Globular clusters, though displaying a general similarity of appearance, differ in stellar content and the distribution of stars composing them. Cluster compactness has provided the basis of a classification scheme based on appearance and used by H. Shapley and H. B. Sawyer, who distinguished 12 classes. Class I clusters have the highest central concentration, class XII the least. The globular clusters are fairly evenly divided among all 12 classes, with some tendency for fewer clusters to occur in the extreme classes. Apparent ellipticity may be added as a second classification parameter.

**By Physical Properties.**—The integrated spectrum or, alternatively, measurements of integrated brightness at selected frequencies over a wide wave-length range provide one type of index of stellar population. The integrated spectral types estimated by N. U. Mayall extend from mid-A to mid-G type, with the average being F7.6. Published multicolour photometric results are insufficient to provide analogous colour statistics. Other physical properties of the clusters that might be utilized as classification parameters are numbers and properties of variable stars (see below) within the cluster, character of the magnitude-colour diagram of the cluster, etc. Much remains to be learned from such classification parameters and combinations of them.

**Stellar Content of the Globular Clusters.**—Colour-Magnitude or Magnitude Spectral-Type Diagrams.—The stellar content of a cluster can be determined if for large numbers of individual stars in the cluster there are established at least two properties: magnitude (or brightness) and colour, or magnitude and spectral type. Fig. 2 displays a schematic magnitude-colour diagram for a typical globular cluster. The brightest stars in the globular cluster are red, cool stars. There are no very bright blue, hot stars so characteristic of the great majority of galactic clusters. The hot, blue stars (some are exceedingly blue) in the globular clusters are intrinsically very much fainter than stars of the same colour located in the vicinity of the sun. In fact, in the globular clusters (see fig. 2) the bluer a star, the fainter it is. In the solar neighbourhood, the bluer a star, the brighter it is.

The magnitude-colour diagram of a globular cluster bears little resemblance to the magnitude-colour diagram of stars found in the vicinity of the sun. It is, presumably, characteristic of the nuclear region of the galaxy.

**Variable Stars.**—The presence of great numbers of variable stars in globular clusters was demonstrated by S. I. Bailey of Harvard College observatory. The overwhelming majority of the more-than-a-thousand variables known in globular star clusters have periods of less than a day. These are the cluster type or RR Lyrae variables; they occur only in the small region of the magnitude-colour plane (fig. 2, labeled variable star gap).

FIG. 2.—SCHEMATIC MAGNITUDE-COLOUR DIAGRAM OF GLOBULAR STAR CLUSTER  
Shaded areas indicate regions of the plane occupied by globular cluster stars. Variable star gap indicates region in which cluster variables occur

stars that fall in this narrowly defined region are variable stars. The light variation of a cluster-type variable is caused by pulsation; i.e., by rhythmic contraction and expansion of the star.

Globular clusters differ markedly in their variable star content. Thus, the well-known cluster  $\omega$  Centauri contains in excess of 160 cluster variables, while 47 Tucanae contains almost none.

Over 100 periodic or semiregular variables with periods longer than one day are known in globular clusters; they are brighter than the cluster-type variables. Approximately half of these stars have periods between 1 and 40 days; they may be regarded as Cepheidlike variables characteristic of the globular-cluster population.

It is remarkable that in all the known globular clusters only three eclipsing variable stars have been discovered. Conditions within globular clusters, unlike conditions within galactic clusters and the neighbourhood of the sun, are apparently unfavourable for the formation of double stars.

The cluster-type variables in a cluster are all of very nearly the same brightness. Under the assumption that the brightnesses of these stars are the same from one cluster to another and, further, that they are the same as the brightnesses of the RR Lyrae stars in the solar vicinity, the astronomer possesses a powerful means of determining globular-cluster distances. He can, from the measured motions and apparent brightnesses of the RR Lyrae stars in the vicinity of the sun, calibrate or determine the brightnesses of these nearby variables. He can then measure the apparent brightnesses of the cluster-type variables in a globular cluster and from the difference in the apparent brightnesses of the variables in the cluster and the derived brightnesses of the nearby variables infer the distance of the globular cluster. The cluster distances measured in this way range from 12,000 to more than 100,000 light-years.

The determination of these enormous distances with a reasonable degree of accuracy constitutes one of the triumphs of modern astronomical investigation. A new era in the astronomer's understanding of the galaxy began when Shapley used such distances to investigate the space distribution of the globular clusters and, from that distribution, derived the direction of and distance to the galactic centre.

**Spectral Characteristics of Stars in Globular Clusters.**—The spectra of stars in globular clusters differ from those of stars in the solar neighbourhood or in galactic clusters. In globular cluster stars the spectral lines arising from the metals are very weak. This fact has caused difficulties in assigning spectral types to individual stars in clusters, especially when small dispersion spectra have been employed. The degree of line weakness appears to be consistent within any one globular cluster but to differ from one cluster to another.

The phenomenon of the weak spectral lines of the metals in stars in globular clusters may be explained in terms of an underabundance of metals (taking the local stars as normal), ranging from a factor of 20 to 200 or more in different globular clusters. Such a difference in the abundances of the elements in stars in globular clusters and in galactic clusters (and in different parts of the galaxy) must arise from differences in the composition of the primeval material from which the stars were formed. The differences constitute an important fact to be included in any theory of the formation and evolution of stars in the galaxy.

**Size and Structure of Globular Clusters.**—Specification of a precise diameter for a globular cluster is difficult. The stars simply thin out at greater and greater distances from the cluster centre. The linear diameters of different globular clusters range from 50 to 300 light-years, not counting the outermost stars. Clusters rich in stars are generally larger than those poor in stars. The space density of stars in all globular clusters is very much higher than it is in the general region of space around the sun or even in galactic star clusters.

A typical globular cluster is slightly flattened, as though the cluster were rotating. The flattening reveals itself through the elliptical form of the projected image of the cluster, a directly observable quantity. It is not possible to determine independently the true flattening of a cluster and the inclination of its equatorial

plane to the line of sight. However, it is possible to say, from the results at hand, that some clusters have equatorial diameters at least 25% greater than their polar diameters.

The kinetic theory of gases has stimulated much work on the statistical laws governing the distribution of stars in globular clusters. No completely satisfactory representation of an observed distribution law has yet been found. The studies that have been made, of course, have involved only a few thousands of the brightest (and more massive) stars. The fainter objects in the globular star clusters have not been adequately considered in any of these treatments.

## GALACTIC STAR CLUSTERS

**Number of Galactic Clusters in the Galaxy.**—The galactic clusters located in the flat-disk portion of the galaxy and concentrated in the spiral arms of the galaxy are far more numerous than the globular clusters. The catalogue published by Alter, Ruprecht and Vanysek listed 576 galactic star clusters, but in contrast to the situation of the globular clusters only a very small portion of the existing galactic star clusters have been found. The reason is, of course, that the galactic star clusters are located in the part of the Milky Way in which much dark obscuring material exists; we can therefore survey only a small portion of the total volume of the Milky Way in which these clusters are located. It is estimated from statistical studies that at least 40,000 galactic clusters exist throughout the entire galaxy.

**Classification of Galactic Clusters.**—By *Appearance*.—The general purpose of any classification of clusters made on the basis of appearance is to make possible selection of homogeneous groups of objects. Among the classification schemes proposed for the galactic clusters, the one by R. J. Trumpler has been the most successful. He assigned three-symbol designations to each cluster on the basis of: (1) the degree of central concentration (consideration was given to the fact that the cluster was "detached" or involved in a dense star field); (2) the range in luminosity of the cluster stars; (3) the number of stars contained in the cluster. Further notations were employed to indicate peculiarities (elongated or unsymmetrical form, nebulousity, etc.) of a few clusters. Clusters that have the same three-symbol designation in this system appear to be quite similar in linear dimensions.

By *Physical Characteristics*.—Trumpler also devised a classification scheme based upon the nature of the magnitude-spectral-type diagrams of the clusters. Typical diagrams are exhibited in fig. 3. A two-symbol designation characterizes the cluster.

Class 1 includes those clusters that contain main sequence stars. Class 2 clusters have a small or moderate number of red giant stars in addition to main sequence stars. Class 3, of which there are few examples, is composed of clusters in which the number of giant stars is very considerable.

In each of these three classes the clusters may again be distinguished by the earliest spectral type found in the cluster. For example, 1B3 designates a cluster composed of main sequence stars, the earliest of which is B3.

Trumpler made the significant discovery that in this classification scheme not all classes are occupied. He found no class 2 objects with stars earlier than B4, for example. This classification scheme relates to the larger, more general questions of the stellar content of the clusters, which, we know now, relate directly to cluster age. Trumpler's discoveries have given impetus to studies of stellar evolution.

**Stellar Content of the Galactic Clusters.**—An outstanding characteristic of the galactic star clusters is that they are much richer in highly luminous stars than the general solar neighbourhood, even though they are found in the same region of the galaxy as the sun. Stars in clusters are often thousands of times more luminous than the sun; in fact, the clusters contain some of the most luminous stars known. The clusters are also found to be much more frequently associated with gas and dust, which appear as bright nebulousity when illuminated by the cluster stars, than would be expected on the basis of chance alone.

Recent observations of the colour-magnitude diagrams of galac-

FIG. 3.—TRUMPLER'S CLASSIFICATION OF GALACTIC STAR CLUSTERS  
Diagrams showing two principal classes 1 (above) and 2 (below), with two spectral types, or subclasses, for each class. Shaded areas indicate areas of the plane occupied by stars in galactic clusters

tic clusters (see fig. 4) indicate the kinds of stars found within the clusters and illustrate in detail Trumpler's classification scheme as well. Of particular interest is the position of the turnup of the upper portions of the main sequences of the clusters, a feature early noted by Trumpler and now known to be related to cluster age. The great majority of galactic clusters observed

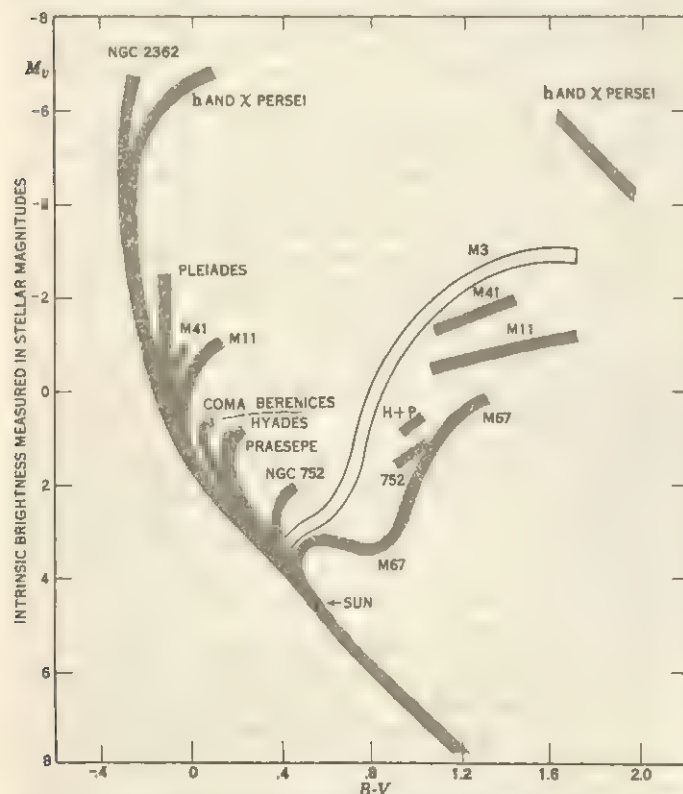

FIG. 4.—COMPOSITE MAGNITUDE-COLOUR DIAGRAM OF GALACTIC AND GLOBULAR STAR CLUSTERS. M3 IS A GLOBULAR CLUSTER; OTHERS ARE GALACTIC CLUSTERS. THE POSITION OCCUPIED BY THE SUN IS INDICATED

are far younger than the globular clusters or, presumably, than the general group of stars forming the main body of the galaxy. As a star grows old, its brightness and colour change. The forms of the main sequences of the various clusters have given us our most valuable observational evidence of the shapes of the evolutionary paths in the colour-magnitude plane followed by stars of different masses.

Investigations of the numbers of stars of different brightnesses in the galactic clusters show that, in comparison with the stellar population in the region of the sun or in the globular star clusters, there is a great deficiency in the numbers of faint stars in the galactic cluster. This phenomenon, reflecting the way in which matter breaks up into stars, must arise from differences in conditions obtaining: (1) very long ago when the globular clusters and the stars in the general body of the galaxy were formed; and (2) more recently when the majority of galactic clusters condensed out of the interstellar medium. Such evolutionary problems as these are among the central ones of modern astronomical investigation.

**Variable Stars in Galactic Clusters.**—Galactic clusters contain very few intrinsically variable stars; they do contain a significant number of double stars, which are observed as spectroscopic binary stars or eclipsing variables.

The small population of intrinsic variable stars in galactic clusters differs radically from that observed in the globular clusters. Galactic clusters contain no RR Lyrae variables, which are numerous in globular clusters. However, they do contain a few Cepheid variable stars. These galactic-cluster Cepheids appear to be identical in nature with the classical Cepheid variables found in the solar neighbourhood. The galactic clusters do not contain any counterparts of the periodic or semiregular variables that are found in the globular clusters and that have periods longer than one day.

Like the differing colour-magnitude diagrams of the galactic and globular clusters, the differing variable-star populations of these two types of clusters indicate that globular and galactic clusters are objects that are very different in stellar content and physical characteristics. Their ages and their past histories must also be quite different.

**Strange Stellar Types in Young Clusters.**—The stars in galactic clusters are generally similar to the stars in the vicinity of the sun with respect to spectral and other physical characteristics. Notable exceptions to this rule occur in some very young clusters, which characteristically contain very bright stars and are frequently associated with extensive clouds of dust and gas. They also contain strange stellar types—stars that, as judged on the basis of the common variety of nearby stars, are too red (too cool) for their brightness (roughly solar brightness or fainter). In some instances these young groups contain examples of the very interesting T Tauri variety of erratic intrinsic variable stars. The T Tauri variables have intrinsic brightnesses similar to, or fainter than, the sun; their spectral types are G or later. It is presumed that these strange stellar types represent stars less fully developed than stars of similar masses in older clusters or in the vicinity of the sun. Much remains to be learned from the study of such stars.

**Sizes and Structure of Galactic Clusters.**—The limiting diameters of galactic clusters vary between 15 and 75 light-years; the richer clusters are larger than the poor ones. Stars of different brightnesses or masses do not show the same space distribution throughout the cluster. The brighter (more massive) stars within any cluster are generally found concentrated near the centre of the cluster. The fainter (and less massive) stars are spread over a larger volume of space and indicate a larger diameter. The apparent diameter of a cluster estimated on a photograph is generally no more than one-third of the limiting cluster diameter for the faint stars. The galactic clusters are far less regular in form than the globular clusters. Diameters are therefore especially difficult to estimate.

In the central, and therefore denser, parts of galactic clusters each star is, on the average, separated from its nearest neighbour by a distance of approximately  $1\frac{1}{2}$  light-years. However, in the central portion of rich clusters the space density of stars is at

least a hundred times as great as the space density of stars in the solar neighbourhood. If we were to construct a model of an average galactic cluster, using pinheads for stars, we should require a few hundred pins. We should then have to scatter these throughout a sphere approximately 150 mi. in diameter. On the average, the pinheads would be some 4 or 5 mi. apart.

**Disintegration of Galactic Star Clusters.**—The stars in a cluster continuously interact gravitationally; they are in continuous motion. Chance close encounters between stars produce strong perturbations in their motions. As a result of such perturbations a star may be given sufficient velocity to escape from the gravitational field of the cluster. Through such "evaporation" of stars a cluster shrinks both in linear size and in stellar content. Very general considerations show that the stars of small mass evaporate from the cluster more rapidly than those of large mass. Even if they do not gain enough energy to evaporate from the cluster, the small-mass stars will tend to move to greater-than-average distances from the cluster centre because of perturbations; they form an extended halo about the cluster. This theoretical prediction may provide at least a partial explanation of the observation that the fainter members of a cluster occupy a larger volume of space than the brighter and more massive members.

The cluster tends to be disrupted by the differential rotation of the galaxy, as well as by the chance encounters that occur between a cluster and the complexes of dark material and stars as the cluster moves in its orbit around the galactic nucleus. The encounters between the cluster and cloud-star complexes produce more important disintegration forces than the differential galactic rotation. The smaller the diameter of the cluster and the greater the total mass of stars in the cluster the longer the time required for disruption. For a cluster like the Pleiades, the disruption time is of the order of 1,000,000,000 years.

**STARETS** (plural *startsy*), a holy man, usually a monk, commanding wide popular respect for his gift of spiritual guidance, in the Russian church of the 18th and 19th centuries. The fact that most of the *startsy* were monks meant that their influence was unconnected with priesthood. They were mainly simple people who relied on direct guidance from the Holy Spirit and were not connected with the official church hierarchy. The Church Slavonic word *starets* in the Middle Ages was simply a translation of the Greek word *geron*, which, in the Orthodox world, meant no more than "monk." However, with the advance of the hesychastic movement (see HESYCHASM), which aimed essentially at a reformation after the monastic ideal of the ancient eremitic settlements in the Egyptian and Palestinian-Syrian deserts, the word began to signify especially that type of aged monk whose "inward activity" (*noera ergasia*) of contemplation was so far developed that he was chosen by younger monks as a spiritual leader. The way of life of the skete (ascetic settlements grouped round a common church), arising in connection with this reforming movement, encouraged the *starets* in this special sense.

The first great *starets* on Russian soil was Nil Sorski (q.v.), who preached the skete manner of life to Russian monks. His disciples, the Transvolgian *startsy*, concerned with the purely ascetic, moral way of life, were defeated in a dispute with the Josephites (followers of Joseph, abbot of Volotsk), who clung to

the public functions of the monasteries; e.g., care of the poor and aged and the training of young men for the church hierarchy. The ideals of ascetic sanctification, however, were kept alive in the desert monasteries through the writings of Nil Sorski, and in the 18th century they produced the true Russian *starets* in the narrow sense of the word. This development was assisted by the neohesychast ideas from Mt. Athos, which the *starets* Paisy Velichkovsky (d. 1794) introduced to the Slav world through his Church Slavonic translation of the hesychast *Philokalia* (q.v.) of Nikodimos Hagioritis.

A further step was taken when *startsy* became not merely spiritual leaders inside the monasteries but also pastors and counselors of the laity (see also SERAPHIM, SAINT). People now began to make pilgrimages to the *startsy*, the most famous of whom were those of the monastery of Optina Pustynye, in central Russia: Leonid (d. 1841), Makarios (d. 1860), and Ambrosius (d. 1881). Also important for Russian spiritual life in the 19th century were the two former bishop *startsy*, Ignatius Bryanchaninov (d. 1867) and Feofan Zatvornik (Theophanes the Recluse; d. 1894), the first for his ascetic writings and letters and the second for his modern Russian edition of the *Philokalia*. A fine example of the type of spirituality produced by the *startsy* teaching is the anonymous 19th-century *Way of a Pilgrim*. Dostoevski made the *startsy* famous in world literature by his *starets* Zossima in *The Brothers Karamazov*. See also MONASTICISM: Christian Monasticism: Eastern Monasticism.

**STARFISH** and sea star are names given to radially symmetrical, more or less star-shaped, bottom-dwelling animals found on the margins of almost all seas. They constitute the class Asteroidea of the phylum Echinodermata. Sea stars, which range from the tide lines to depths of 19,700 ft. (6,005 m.), are particularly abundant in numbers and species along the rocky coasts of the North Pacific. In size they vary from ½ in. to 3 ft. (0.9 m.) in diameter. The commonest colours are shades of yellow, orange, pink, or red; but gray, green, blue, and purple forms are also known.

The body is more or less flattened, with the mouth located centrally on the underside. From the body project a number of radially arranged arms, usually 5, but in a few species up to 44, as in the South American genus *Heliaster*, which looks like a giant sunflower. In the tropical cushion star *Culcita* and in many cookie stars, the body is simply pentagonal, whereas in other species the arms may be long and snakelike, as in some of the deepwater forms that live on mud. Along the midline of the arm, on the underside, runs the ambulacral groove, which shelters the numerous, fluid-filled tube feet and the radial water canal from which they originate. Beneath the radial canal lies the skeleton, rows of narrow ossicles united by muscles. The sides of the arms are edged by two rows of plates, the marginals, which in the more primitive forms are large and conspicuous and give a certain rigidity to the arm. In more advanced forms, these plates are small and the arms possess a greater flexibility. The upper side of the body and arms has a skeletal cover of different types, suitable to the animal's mode of life. In forms that hide in sand, the surface is often covered by plates with bundles of spines, giving a brushlike effect; in others, imbricating scales are present; and in the most modern and quick-moving forms, the skeleton is a loose-meshed network of ossicles, with or without projecting spines. Usually conspicuous on the upper side is the madreporic plate, through which water is taken into the water vascular system by means of ciliated pores. Many sea stars possess pedicellariae, spines modified into pincers. In their simplest form they are pairs or rows of spines that can be moved against each other; in more advanced species they are stalked, of complex structure, and often present in enormous numbers, especially on the vulnerable upper side of the animal. Pedicellariae remove dirt from the surface, pass food down to the mouth, and defend the animals against enemies. In the more active forms like *Asterias* and its relatives, the body surface is increased by numerous respiratory extensions from the body cavity; in species where they are really

well developed, these extensions may form a "velvet" over the upper surface. In the dry specimen their place is indicated by pores between the ossicles.

The sea stars have a large stomach, divided into a cardiac and a pyloric part. In many forms there is no intestine and no anus. In the more advanced forms, large digestive glands are present, extending into the lumen of the arms. The sex glands open by pores between the arms. In most forms, enormous numbers of eggs and sperms are set free. The free-swimming larva, the bipinnaria, is of relatively simple form, indicating that the sea stars are comparatively primitive echinoderms. After a shorter or longer period, during which it may be carried afar by the ocean currents, the larva undergoes a drastic metamorphosis and settles down as a bottom form. Many species, particularly cold-water forms and those from deep water, have large eggs that undergo direct development. Some of these "brood" their young by crouching over them. In one species the eggs are taken into the mother's stomach, where the young develop; the mother ceases to take in food during the incubation period.

The class is quite successful, with about 1,200 known species. Because of their rather fragile skeletons, sea stars do not preserve well as fossils, and are therefore rather incompletely known from earlier geological periods. Many, particularly the more primitive forms, live at great depths, often on muddy bottoms, and take most of their food in along ciliated grooves, which carry the minute, decaying particles to the mouth. In shallow water, particularly on rocky coasts, the more modern forms abound, with their flexible body, increased number of tube feet, and often eversible cardiac stomach. They are often found where there is an abundance of bivalves (oysters, clams, mussels) and are responsible for considerable damage in commercial bivalve beds.

The sea star's ability to open a bivalve by pulling the shells apart has been known for centuries. The feat is accomplished by the sea star affixing itself by its tube feet to the two shells, applying "pull" to separate the shells—a fraction of an inch is enough—and squeezing a part of its eversible stomach into the interior. The victim, adversely affected by the stomach fluid secreted by the sea star, opens its shells wider, allowing the predator to insert more of its stomach and to complete the digestion of the soft tissue.

Where commercially important bivalves occur in quantities, continuous efforts are made to prevent sea stars from entering these areas, and to remove them by dragging nets over the bottom. Their power to regenerate missing arms is spectacular, some sea stars being able to re-form completely from as little original tissue as the mouth framework (see REGENERATION). Where fishnets are left untended for any length of time, sea stars may move in and devour a large amount of the catch; they are also known to enter lobster pots and eat the bait. Sea stars are acceptable as food only to a few animals. For man they are utterly useless, except where large quantities are gathered and used as a lime-yielding fertilizer.

**STARK, JOHANNES** (1874–1957), German physicist who in 1919 received the Nobel Prize for Physics for his discovery that spectral lines are distorted in an electrical field—the so-called Stark effect (*q.v.*). He was born April 15, 1874, at Schickenhof, Bavaria. He studied at Munich and in 1900 became an assistant at the University of Göttingen. He went as professor in 1909 to the technical college at Aachen, in 1917 to Greifswald and in 1920 to Würzburg. He retired in 1922. Stark devoted himself principally to the study of the modern theory of radiation and the atomic theory. He discovered the Doppler effect in parallel rays, for which the Vienna Academy awarded him the Baumgartner Prize in 1909. His essays include "Prinzipien der Atomdynamik" (1910–15); "Die elektrischen Quanten, Die elektrische Strahlung, Die Elektrizität in Gasen" (1902); and "Atomstruktur und Atombindung" (1928). Stark was the founder of the *Jahrbuch für Radioaktivität und Elektronik* (1904), which he edited until 1919. A supporter of Hitler and an anti-Semitic racial theorist, he was president of the Reich Physical-Technical Institute, 1933–39. In

1947 a denazification court sentenced him to four years in a labour camp. He died at Traunstein, Bavaria, June 21, 1957.

**STARK, JOHN** (1728–1822), U.S. general during the American Revolution, was born at Londonderry, N.H., on Aug. 28, 1728. During the French and Indian War he served till 1759 in Rogers' Rangers, as a lieutenant and, later, captain. At the outbreak of the American Revolution, he was named a colonel and fought at Bunker Hill, in the invasion of Canada, and in New Jersey. In March 1777 he resigned his commission, but when English Gen. John Burgoyne invaded New York he was made brigadier general of militia and defeated two Hessian detachments near Bennington, Vt., on Aug. 16, 1777. For this victory Stark was given the rank of brigadier general in the Continental Army. He helped force the surrender of Burgoyne at Saratoga in October 1777 and for a short time was commander of the northern department. He served in Rhode Island in 1779 and at the battle of Springfield, N.J., in 1780. In September 1783 he was made a major general. He retired to his farm and died at Manchester, N.H., on May 8, 1822. (H. H. P.)

**STARK EFFECT** is the splitting of spectral lines observed when the radiating atoms, ions, or molecules are subjected to a strong electric field. Soon after P. Zeeman discovered the magnetic splitting of spectral lines the electric analogue of the Zeeman effect (*q.v.*) was sought by many physicists, but success came first to Johannes Stark (*q.v.*) in 1913. The earlier experiments failed since a strong electric field could not be maintained in conventional spectroscopic light sources (see SPECTROSCOPY) because of the high electrical conductivity of luminous gases or vapours. Stark observed the hydrogen spectrum emitted just behind the perforated cathode in a canal-ray tube. By placing a second charged electrode parallel and close to this cathode he was able to produce a strong electric field in a space of a few millimetres. At low gas pressure the mean free path of the atoms was much greater than the distance between the plates so that few conducting ions could be produced by collisions. In an electric field of the order of 100,000 v. per centimetre Stark observed, with a spectroscope pointing across the field, that the Balmer lines of hydrogen were split into a number of symmetrically spaced components, some of which were linearly polarized parallel to the lines of force, the remainder being polarized perpendicular to the direction of the field. This transverse Stark effect resembles in some respects the transverse Zeeman effect, except that the separations (in wave numbers per volt in the first case, per oersted in the second) are larger, the number of Stark levels increases with electron-shell number (*i.e.*, principal quantum number), and the intensity distribution among the components is different. A satisfactory explanation of the Stark effect in hydrogen, given in 1916 independently by K. Schwarzschild and by P. Epstein, was a great triumph for quantum mechanics (*q.v.*).

The Stark effect was also observed in the spectra of metals by employing special (LoSurdo) tubes containing a cathode of the metal under investigation, and viewing the light emitted near the cathode where a large potential gradient exists. In general, the electric splitting in spectra of metals is small compared with that in hydrogen, and unlike the Zeeman effect, which is symmetrical in spacing and intensity distribution of components, the Stark effect is usually only a displacement of unresolved components toward greater or smaller wavelengths. This effect does not depend in a simple way on the nature of the combining atomic energy levels and for this reason the Stark effect in comparison with the Zeeman effect has little practical value in the analysis of complex spectra or of atomic structure. (W. F. M.)

See H. G. Kuhn, *Atomic Spectra* (1962); H. J. Tobler *et al.*, "Distortion of Line Shapes in Stark Modulated Microwave Spectrometers," *J. Scient. Instrum.*, vol. 42 (1965).

**STARLEY, JAMES** (1830–1881), whose inventions earned him the title of "father of the cycle industry," was born at Albourne, Sussex, Eng., on April 21, 1830, and was educated in the village school. After working on the land in Kent he went in 1855 to London where he was employed in the manufacture of sewing machines, and then moved to Coventry, where he became managing foreman at the Coventry Sewing Machine Co. (later

the Coventry Machinists' Co. Ltd.) and patented new models.

In the late 1860s, however, he became interested in the early forms of bicycle then appearing (through his firm's manufacture of *velocipèdes* first for the French and later for the British market). Starley's first invention was the "C" spring and step machine, popularly known as the Coventry model. He followed this success in 1871 with the Ariel bicycle, notable for its centre pivot steering; then the Tangent; and, in 1876, the still excellent Coventry tricycle. Starley also invented the double-throw crank, the chain, and the chain wheel drive, all of which became standard parts of every bicycle.

Starley died at Coventry on June 17, 1881. See also BICYCLE: The "Ordinary" Bicycle.

**STARLING, ERNEST HENRY** (1866–1927), English physiologist, one of the foremost of his age, was born in London, April 17, 1866. Educated at King's College school, he entered Guy's hospital in 1882 and graduated M.D. in 1890. In that year he was appointed lecturer in physiology at Guy's. He was elected a fellow of the Royal society in 1899, and in 1900 became Jodrell professor of physiology at University college, London, where he worked until, in 1922, he retired from the Jodrell chair and was appointed Foulerton research professor of the Royal society.

The subjects for investigation that particularly attracted Starling were those physiological processes that seemed capable of interpretation in terms of chemistry and physics. The conditions determining transudation from the vessels and lymph flow occupied his attention for several years, and he showed that the hydrostatic and osmotic pressures within the vessels supplied the balance of force necessary to explain the previously perplexing experimental facts. His researches on the movements of the intestines, in conjunction with Sir William Bayliss (*q.v.*), demonstrated the neuromuscular mechanisms involved. Their discovery of secretin not only laid bare the way in which the secretion of the pancreas was called forth and adjusted, but also stimulated further research on the chemical integration of the body functions. By ingenious experimental methods Starling was successful in maintaining the mammalian kidney, isolated from all connection with the body, in a state of functional activity, thereby bringing to light new facts concerning renal secretion. His most important researches, however, were those dealing with the heart and circulation. He demonstrated the mechanism by which the heart is able to increase automatically the energy of each contraction in proportion to the mechanical demand made upon it and, apart from the nervous system, to adapt its work to the needs of the body.

During World War I Starling was director of research at the Royal Army Medical Corps college and engaged in devising defensive methods against poison gas. Subsequently, 1917–19, he was chairman of the Royal society's food committee, scientific adviser to the ministry of food and British scientific delegate on the Inter-Allied Food commission. He died on May 2, 1927.

**STARLING**, the name for birds of the passerine family Sturnidae, which contains about 103 species. The normal range of the family is Africa, Europe and Asia, to Australia, with most species in the tropics. Certain species have been introduced into various other parts of the world, such as Madagascar and Hawaii, and into North America, where the common starling of Europe, *Sturnus vulgaris*, is widespread.

Dark, iridescent plumage characterizes many starlings, but duller birds exist, and one species is mostly white. Bare, coloured areas of skin, or wattles, decorate the heads of some. Certain species of the tropical forest are mostly arboreal and eat fruit; those of open country walk about on the ground and eat insects. Several species are familiar birds, coming about houses and gardens, where they may cause annoyance by usurping the nesting sites of other birds.

JOHN H. GERARD  
STARLING (*STURNUS VULGARIS*).  
COMMON TO EUROPE AND NORTH  
AMERICA (WINTER PLUMAGE)

Gregariousness is a common trait. The birds may feed or roost in large flocks, and some nest in colonies. The nest may be in a hole in a tree, bank or building or may be an oval, pensile structure. The eggs are plain or spotted.

A number of starlings are kept as cage birds, notably the talking mynas and several other southeast Asian species. The African oxpeckers, genus *Buphagus*, that eat ticks off the skin of hoofed animals are aberrant starlings. See also BIRD. (A. L. RD.; X.)

**STAR-SPANGLED BANNER**, the national anthem of the United States of America. It was officially adopted by an act of Congress signed by Pres. Herbert Hoover on March 3, 1931, although it had been in common use for well over a century before that date. The words were written by an American lawyer, Francis Scott Key (*q.v.*), Sept. 13–14, 1814. The music, long a subject of considerable controversy, is now generally credited to the British composer, John Stafford Smith (1750–1836). The argument that Samuel Arnold, Smith's predecessor as organist of the Chapel Royal, was the composer was effectively answered by Oscar G. Sonneck, chief of the Division of Music of the Library of Congress in a report in 1914.

The original version of the melody was written for a social club, the Anacreontic Society of London, with the title "To Anacreon in Heaven," with words by the organization's president, Ralph Tomlinson, probably about 1780. There were no less than five early publications of the words and music without credit to the composer, but in 1799 the combination appeared in Smith's *Fifth Book of Canzonets, Catches, Canons and Glees*, as "harmonized by the author," and since all the other melodies were of his own creation, there seems to be no reason for making an exception of "the Anacreontic Song."

This historic ditty naturally lauded the Greek poet Anacreon, the Society's patron saint, who wrote mostly about wine and women, as emphasized in the closing couplet of each stanza, which urged the members to "entwine the myrtle of Venus with Bacchus's vine." It is not generally realized that the Anacreontic tune was used many times, with a variety of words of political, patriotic, social, and sometimes ribald, nature. Richard Hill, a successor to Sonneck at the Library of Congress, reported the discovery of more than 80 such texts for this one melody.

The outstanding American adaptation of "To Anacreon in Heaven" (before "The Star-Spangled Banner") was a song called "Adams and Liberty," written for the presidential campaign of John Adams by a certain Thomas Paine, who called himself Robert Treat Paine, Jr., to avoid confusion with his more famous namesake. The same author used the Anacreon tune again as the musical setting of a poem entitled "Spain," and it is logical to assume that Francis Scott Key was familiar with one or both of these songs.

The story of Key's creation of his immortal lines has often been told, with some conflicting details. The significant facts are that the young lawyer, then living in Georgetown, near Washington, D.C., was asked to negotiate with the British Navy for the release of his friend, William Beanes, of Upper Marlborough, Md., a doctor who had been taken into custody as a result of his own highly irregular arrests of stragglers from the invading British army. According to Key's own account, he was taken on board one of the British ships that were then preparing for an attack on Baltimore by way of Fort M'Henry (or M'Henry as it was often written). Obviously neither he nor Beanes could be released until the battle had taken place, and thus the stage was set for the all-night vigil of Sept. 13–14, which inspired the poem first called "The Defence of Fort M'Henry" and eventually "The Star-Spangled Banner."

Francis Scott Key watched the bombardment by the light of bombs (as artillery shells were then called) and rockets; at dawn he saw that the American flag was still flying over the fort, proof that the fort had not been captured. Using the back of an envelope, Key started writing his poem while on board the British ship. He continued it in the small boat that later took him and Beanes ashore and finished it at a hotel in Baltimore. He showed it to his brother-in-law, Judge J. H. Nicholson, who immediately had it printed and distributed in

broadside form. "The Defence of Fort M'Henry" appeared in the *Baltimore Patriot* of Sept. 20, 1814, and the following day also in the *Baltimore American*, both papers indicating that it should be sung to the tune of "To Anacreon in Heaven." The title was soon changed to "The Star-Spangled Banner," appearing thus in the 1814 catalogue of Carr's Music Store in Baltimore and in several popular "songsters" (collections) of the same year.

An actor named Ferdinand Durang is given credit for having sung "The Star-Spangled Banner" for the first time in public, at a tavern next to the Holiday Theatre, where it soon became a regular feature of the performance. Durang claimed that he fitted the Anacreon tune to the words, but little fitting was required because Key clearly had this music in mind when he wrote the words. He had, in fact, written an earlier song, "The Warrior's Return," to the same melody.

The music of "The Star-Spangled Banner" has been criticized on the ground that it covers too great a range (an octave and a fifth) for a song meant to be sung by everyone. Difficult it undoubtedly is, but in the key of Bb, A, or Ab, it is by no means unsingable. Innumerable publications of the song through the years have shown variations in both words and music. An official arrangement was prepared by John Philip Sousa for the U.S. Army and Navy, and music educators have spent much time and effort in arriving at a practical version for American schools. The second and third stanzas are customarily omitted out of courtesy to the British. The accepted text of "The Star-Spangled Banner" is as follows:

Oh, say can you see by the dawn's early light  
What so proudly we hail'd at the twilight's last gleaming,  
Whose broad stripes and bright stars through the perilous fight  
O'er the ramparts we watch'd were so gallantly streaming?  
And the rockets' red glare, the bombs bursting in air,  
Gave proof through the night that our flag was still there.  
Oh, say does that star-spangled banner yet wave  
O'er the land of the free and the home of the brave?

On the shore dimly seen through the mists of the deep,  
Where the foe's haughty host in dread silence reposes,  
What is that which the breeze, o'er the towering steep,  
As it fitfully blows, half conceals, half discloses?  
Now it catches the gleam of the morning's first beam,  
In full glory reflected now shines in the stream.  
'Tis the star-spangled banner, oh, long may it wave  
O'er the land of the free and the home of the brave!

And where is that band who so vauntingly swore  
That the havoc of war and the battle's confusion  
A home and a country should leave us no more?  
Their blood has wash'd out their foul footsteps' pollution.  
No refuge could save the hireling and slave  
From the terror of flight or the gloom of the grave,  
And the star-spangled banner in triumph doth wave  
O'er the land of the free and the home of the brave.

Oh, thus be it ever when freemen shall stand  
Between their lov'd home and the war's desolation!  
Blest with vict'ry and peace may the heav'n-rescued land  
Praise the power that hath made and preserv'd us a nation!  
Then conquer we must, when our cause it is just,  
And this be our motto, "In God is our Trust,"  
And the star-spangled banner in triumph shall wave  
O'er the land of the free and the home of the brave.

(S. Sp.)

**STARVATION** is a state of extreme malnutrition caused by the long-continued deprivation of essential nutrients. It usually results from insufficient food intake, either because food is not available or because the person is unable to eat, due to illness or other factors. Starvation may also result from disturbances in digestion, absorption or utilization of food. See **MALNUTRITION**; **FAMINE**.

**STASSFURT**, a *Kreisstadt* (county capital) of East Germany in the *Besirk* (district) of Magdeburg, German Democratic Republic. Pop. (1964) 24,803. The town is 25 mi. (40 km.) S of the district capital, Magdeburg, and on the Bode River. It is a railway junction and has chemical, engineering, scientific apparatus, and radio equipment enterprises. It is chiefly known, however, for its potash mines and the exploitation of other rock salts. The chronicles note the existence of salt deposits as early

as 1227. The mining of potash salts began in 1861; since then Stassfurt has been known as the cradle of the German potash mining industry. First mentioned in the chronicles in 810, it received its municipal charter in 1276, when it was transferred from the duchy of Saxony to the archbishopric of Magdeburg. From 1680 it belonged to the electorate of Brandenburg, and between 1807 and 1813 to the kingdom of Westphalia.

**STATE.** When the first studies of organized political society were made in Greece, mainly by Plato and Aristotle, in the 4th century B.C., the unit of study was the polis or city-state. The Romans, adapting Greek political ideas, applied them to a larger territorial unit, the *respublica*, which may be freely translated as public concern; or the *status rei publicae*, state of the public concern. It is this Roman application of the term that is most commonly used today. It is altogether probable that we derive the word state from the Roman *status*. In the early 16th century Machiavelli used the term "state" extensively in his works in its modern meaning.

Authorities agree on certain essential properties of a state—population, territory, a government clothed with a monopoly of force for the preservation of peace and order, and having a plenitude of authority within the state independent of external control except that of international law. Since a state cannot function under that law unless it is recognized by the members of the community of nations, such diplomatic recognition is often considered another property of the state. In addition, most political theorists emphasize purpose or end in their definition of the state; this purpose is stated as the promotion of the common good or general welfare.

Two terms are to be distinguished from the term "state," namely, society and nation. The free association of people in families and in social and cultural groupings constitutes a society; these groups lie largely outside of political control. The nation, strictly speaking, is a unit of society with a common language, tradition, and culture that may or may not coincide with state boundaries.

The states of the United States do not constitute states in the accepted meaning of the term. Nor may the term be applied to protectorates or semi-independent commonwealths, such as Puerto Rico. The term "estates-general" derives from the French *états* ("estates"), referring to the various orders or conditions of society, as the clergy, nobility, and third estate or common people, which were represented in European states-general of the medieval period.

**STATE, DEPARTMENT OF:** see **GOVERNMENT DEPARTMENTS**.

**STATE GOVERNMENT (U.S.).** In 1776 the 13 British colonies in America proclaimed themselves to be independent states, and in 1781, under the Articles of Confederation, they formed a "perpetual union." The perpetuity of the union was not assured, however, for the articles which established that "firm league of friendship" provided also that each state should retain its "sovereignty, freedom, and independence," and in the following years the states showed a strong disposition to exercise the sovereignty thus retained. The federal Constitution, drafted in 1787 and put into effect two years later, established a stronger national government, the "more perfect" union that was needed. The Constitution made no reference to the troublesome question of sovereignty, leaving that to be disposed of by time—to be denied to the states, as it turned out, by the Civil War.

**Constitutional Division of Powers.**—The federal Constitution divides the powers of government between the national (commonly called federal) government and the states. The federal government has those powers that are delegated to it by the Constitution and the authority to make all laws that may be "necessary and proper" to implement the powers so delegated. The delegated powers are not numerous, but they are funda-

mental, including those to make war, conduct foreign relations, regulate interstate and foreign commerce, and, of course, to levy taxes. The last-named power may be exercised not only to pay the debts and provide for the common defense but also for the "general welfare." Federal power has been extended little by constitutional amendment, but it has been expanded by the liberal use that Congress has made of the "necessary and proper" clause and by the judicial sanction that has commonly followed such use. It has been said that wars, emergencies, and scientific developments and inventions do not increase federal power, but only furnish the occasion for the exercise of existing powers. As a legal proposition the statement is accurate, yet it would appear to be unrealistic to assume that the almost constant application of power to new conditions and subject matter does not in fact result in increasing power.

In some matters, not all of which are within the legislative power of Congress, federal power and influence have been extended through a system of grants-in-aid to the states. The basic principle is that Congress, acting under its authority to appropriate money for the general welfare or under some more specific authorization, makes funds available to the states for a particular purpose, on condition that the states make appropriations for the same purpose and meet a standard set by Congress in the use of the federal-state funds. The largest federal grants have been made for highway construction, social security, and education.

There are some exceptions, but generally speaking the powers conferred by the Constitution upon the federal government may not be exercised by the states. The Constitution further limits the powers of the states by imposing upon them certain specific prohibitions. For example, the states are forbidden to levy import or export duties or pass any law impairing the obligation of contracts. By far the most significant limitations are those of the 14th Amendment to the Constitution, which stipulates that no state shall "deprive any person of life, liberty, or property, without due process of law; nor deny to any person within its jurisdiction the equal protection of the laws." The force of this restriction becomes apparent when it is remembered that in the United States substantive law as well as procedures must meet the requirements of due process of law.

The states have all powers not conferred upon the federal government by the Constitution and not prohibited by it to the states. The powers of the states are thus residual. Despite the fact that federal power has been steadily increased, the powers left to the states are numerous and comprehensive. The national Congress enacts statutes which define and provide for the punishment of crimes relating to interstate commerce, the currency, national security, and a few other subjects; but the U.S. criminal codes are essentially those of the states. It is true that Congress through its war, currency, banking, taxing, and interstate and foreign commerce powers exercises a wide control over business, but the chartering and regulation of corporations, the laws of contracts, torts, negotiable instruments, sales, and others closely related to the conduct of business are enacted by the state legislatures. Property laws are within the special province of the states, and so are those respecting wills and inheritance. Marriage, divorce, and domestic relations fall within the jurisdiction of the states. The states determine who may vote, provided only that they make no discrimination of the type forbidden by the federal Constitution or laws. Most of the laws regulating political parties and elections are enactments of state legislatures. Local government is established and controlled by the states. Public education is a leading state function. The state is close to the individual. His birth certificate and his burial permit are granted by the state; and as he progresses from the cradle to the grave, the state protects his personal rights and secures his property; carries the major part of the cost of his education; licenses him to enter a calling or a profession; ministers to his convenience in numerous ways; and penalizes his delinquencies.

**Nature of State Governments.**—Each state has a written constitution of its own design, subject only to the requirement that it shall not violate the federal Constitution. State constitutions follow the federal pattern in that they contain bills of rights and

adhere to the cherished American principle of the distribution of powers among the legislative, executive, and judicial branches. Most of the state constitutions provide in considerable detail for both the organization and functions of government and in consequence they are rather long documents, in contrast to the national Constitution. Such elaboration of detail makes frequent amendment necessary, a process that has been pursued with vigour in a number of states.

The bicameral (two-house) legislature is used in all the states except Nebraska, which instituted the unicameral system in 1937. During and for several years following the Revolutionary War, the legislatures enjoyed public confidence and practically unlimited powers in state government. Chiefly because a number of legislatures failed in their trust, the states developed the practice of placing limits on their powers to deal with revenue, appropriations, borrowing, local government, and certain other subjects. Furthermore, in the course of time, the state courts assumed a restrictive view of legislative powers. And finally, between 1898 and 1918, general dissatisfaction with legislatures led more than a third of the states to adopt the initiative and referendum. These limitations do not deprive legislative bodies of essential powers, and they may have the effect of improving their work.

On June 15, 1964, the U.S. Supreme Court handed down a series of decisions of far-reaching importance for state governments. The court ruled that within each state the districts from which state legislators are elected must contain, as nearly as possible, the same number of voters. These decisions, popularly characterized as expressing the "one man, one vote" principle, struck at the overrepresentation of rural areas in many state legislatures and was expected to give greater political power to residents of towns and cities.

In colonial America the governor exercised wide powers; during the Revolution he was stripped of much of his authority; but after about 1850, the tendency was to make him an effective force in legislation, and, since 1915, to strengthen greatly his control over administration. Although his authority over administration has often been impaired by the fact that much of the work of the state has been parceled out to boards, commissions, and other relatively independent agencies, in perhaps half the states this situation has been partially corrected by the establishment of a limited number of administrative departments and the placement of a group of related services in each of them. In such states the department heads are commonly appointed by the governor and serve under his immediate direction, thus giving him an administrative position somewhat analogous to that of the president of the United States. In the great majority of the states the governor's influence over legislation is particularly significant, and it is explained by a variety of factors, including his political position, his permanent and sometimes professional staff, his veto power, and the time limit under which a majority of the legislatures must work. The hand of the governor has been incidentally strengthened by the trend to increase the length of his term.

The system of law and justice in the states was inherited from Great Britain, but it has been modified in the states to fit their requirements. One such modification is in the matter of the selection of judges, most of the states following the elective system and limiting the term of office to four, six, or some other number of years. The courts in all the states follow the practice of judicial review; that is, they pass upon the constitutionality of statutes where such determination is necessary to decision in cases appropriately before them. The administration of justice has fallen short of a desirable standard in some states because of the absence of any central directing authority. Several states rectified this condition by the establishment of a unified court system or by giving a judge of the Supreme Court the authority to assign extra judges in districts with congested dockets and to take other action to expedite the administration of justice. (See COURT: *United States*.)

With some notable exceptions, the states have not been conspicuously successful in meeting the responsibilities imposed by modern developments. For example, many of them neglected to provide for effective local government, to improve standards of

administration, or to modernize the judicial system.

The states in which per-capita income is low find an almost insurmountable difficulty in financing such costly services as highway construction, education, and social security; and, since federal taxes absorb a large part of the taxable income the nation over, even the wealthier states occasionally have difficulties in obtaining adequate revenue.

The states are hardly open to criticism for their failure in matters removed from their control by the revolutionary expansion of commerce and business. Until about 1890 they wrestled alone in the attempt to regulate railroads and other large interstate businesses. It became necessary for the national government to enter the field, using its power over interstate commerce. It may not be said, however, that the states are losing their place in the federal system. If the national government has assumed functions that were formerly left to the states, the states also have greatly expanded their functions, particularly in the direction of education, health, welfare, and public convenience. The states remain vital units of government.

**STATEN ISLAND**, an island of New York, U.S., lying in New York harbour south of Manhattan between New Jersey and Brooklyn; it forms Richmond county and Richmond borough, the third largest of the five New York city boroughs. Triangular in shape, the island has about 35 mi. (56 km.) of waterfront and an area of about 60 sq.mi. (155 sq.km.). Although principally a residential suburb of the Borough of Manhattan and neighbouring New Jersey cities, Staten Island has considerable manufacturing, shipbuilding, oil refining, and metalworking. The borough is connected with Manhattan by the Staten Island ferry, which carries passengers and automobiles; with New Jersey by the Outerbridge Crossing, Goethals, and Bayonne bridges; and with Brooklyn by the Verrazano-Narrows Bridge. Opening of the latter in 1964 added considerable impetus to development of the island. Population (1960) 221,991.

When discovered by Europeans, Staten Island was inhabited by a few Aquehonga Indians, a branch of the Raritans. Beginning in 1630 and during the next three decades several settlements were attempted by such Dutch leaders as Patroon D. P. de Vries, Gov. Willem Kieft (or Kieft) and Cornelis Melyn. These attempts at settlement proved unsuccessful because of Indian attacks which, particularly in 1655, laid waste the white settlements on the island. The first permanent settlement was made in 1661 when the Dutch West India company, having purchased the Staten Island estate of Melyn, granted land to French Waldenses and Huguenots. This settlement was established at Oude Dorp (Old Town), a few miles south of The Narrows.

The island was named during the period of Dutch control for the states-general of the Dutch Republic. Following the acquisition of New Netherland in 1664 by the duke of York, Welsh and English farmers established homes and farms on the island. During the American Revolution Staten Island was the scene of talks between the three representatives of the Continental congress—Benjamin Franklin, John Adams and Edward Rutledge—and Lord Howe in an unsuccessful attempt at reconciliation. This meeting was held at the Billopp or "Conference" house in Tottenville on the southern shore of the island on Sept. 11, 1776. The island was the residence of Giuseppe Garibaldi, the Italian patriot, in the early 1850s during his exile from Italy. After the American Civil War industrialization increased while farming and fishing waned in importance. In 1898 Staten Island became one of New York City's boroughs. (See also **NEW YORK [CITY]**; **RICHMOND**.)

The island has numerous points of interest which include Bar-

rett park, containing the Staten Island zoo; the museum of the Staten Island Institute of Arts and Sciences; the Staten Island Historical museum; the Sailors' Snug Harbor (a home for retired U.S. seamen); and the Billopp or "Conference" house. There are two liberal arts colleges on the island, Wagner college, a Lutheran coeducational institution founded in 1883, and Notre Dame College of Staten Island, a four-year Roman Catholic college for women, established in 1931.

There are many historic churches and houses still standing, among which is the Voorlezer's house (1696), one of the earliest known elementary school buildings in the U.S. (D. L. D.)

**STATES OF THE CHURCH:** see **PAPAL STATES**.

**STATES' RIGHTS**, a phrase used to describe those governmental powers retained by the individual states of a federal union under the provisions of the federal constitution. In the United States, Switzerland, and Australia, these powers are those that remain after the powers of the central government are enumerated in the constitution. In Canada and the German Federal Republic, on the other hand, the powers of both the levels of government are defined by specific constitutional provisions.

In the United States the term states' rights has also been widely used for a variety of political programs. Before the Civil War it was the rallying cry of southern opponents of northern-inspired tariffs and northern proposals to abolish or restrict slavery (see **NULLIFICATION**). By the second half of the 20th century, it had become the catchword of those who opposed integration of Negroes and whites in public schools, and of those who criticized the growing power of the federal government.

The governmental authority actually remaining in the member governments varies greatly among federal systems. It is perhaps greatest in the United States and weakest in countries such as Mexico and Brazil, where most power is concentrated in the central government and the states are little more than administrative agencies. State power declined rapidly after 1900 in the United States, and somewhat similarly in Canada and Australia. The major causes of this trend in the U.S. were the increased activity of the central government through the power of Congress to control interstate commerce, federal financial subsidies to the state governments or their subdivisions, national measures for combating depression, and participation in World Wars I and II.

In general, states' rights suffer more from financial subsidies of the federal government than from the commerce clause. These subsidies sometimes involve substantial central control in fields that are not included in the federal government's enumerated powers. If the state government rejects the subsidy, it presumably damages its area financially. The result of the subsidy process in the second half of the 20th century in the United States was that the federal government exercised varying degrees of influence, ranging from considerable to determinative, in public policy involving vocational education, public housing, airport construction, sewage plant construction, state and local road construction, fish and game conservation, and other fields which a reading of the Constitution would clearly indicate were states' rights. Canadian and Australian experience in the 20th century was similar, the central governments concerned moving through subsidies into many fields of state or provincial action.

Some political scientists believe that a federal system of government (see **FEDERAL GOVERNMENT**) is merely a transitional form that will be ultimately succeeded by unified government. A quick glance at 20th-century federal systems would seem to confirm this view. However, states' rights may persist a long time. In three of the federal countries—the United States, Australia, and Canada—study commissions have concluded that it is desirable to maintain the autonomous authority of the state or provincial governments. The reasons given included the training of the citizenry in democratic processes through state and local self-government, the greater opportunity under a federal system to adapt governmental policies to the needs of particular areas, and the deconcentration of power resulting from a federal system. There was considerable evidence that for these reasons a large number of thoughtful people in the three countries wished to maintain states' rights.

**STATIC**, in radio, a hissing or crackling noise in the receiver that interferes with the desired signal. It may be either natural or man-made, and it consists of spurious electromagnetic waves ranging in frequency from a few hundred cycles per second to many thousand kilocycles. The most common natural source of static is lightning discharges, which may be detected by sensitive AM receivers at distances of more than 1,000 mi. (1,609 km.). Man-made sources of static include automobile ignition systems, electric motors, and any improperly operating electrical equipment in which sparking occurs. Because most static signals are of an amplitude-modulated form, they are not detected by FM receivers. See also RADIO; RADIO RECEIVER.

**STATICS** is a branch of mechanics concerned with the conditions under which a body remains at rest. Although statics relates strictly to both solid and fluid systems, it is common to give special names to the statics of some particular types of deformable bodies. In particular, elasticity and plasticity theory concern specific types of solids, while the statics of liquids is known as hydrostatics. This article is devoted to a brief discussion of the statics of rigid bodies, a subject of critical importance in the design and construction of such objects as bridges, aircraft, buildings, dams, submarines, high-heeled shoes, automobiles, and braces for straightening teeth. The discussion to follow assumes a familiarity with the article MECHANICS.

**A Simple Problem of Rigid Statics.**—Consider the simplest type of railway bridge, consisting essentially of a metal beam supported by two masonry abutments. Suppose that it is wished to estimate the amount of the force transmitted to the stationary beam at one of the abutments. This information might be needed for a variety of reasons, although the designer of the structure would normally postulate some suitable loading of the beam when making strength calculations. This required force can be found from consideration of the statics of the beam, isolated for the purposes of analysis as in fig. 1.

FIG. 1

This beam has forces applied to it: they are its weight  $W$  (a distributed body force) and also the vertical forces  $F_1$  and  $F_2$  transmitted by the supports separated by distance  $l$ . Conditions under which this beam can be in equilibrium are: (1) the resultant force applied to it, in any direction, shall be nil; and (2) the resultant moment of all the applied forces about any fixed axis shall be nil. The beam in fig. 1 is at rest, and mathematical expression may now be given to this fact. Requirement (1) demands that

$$W - F_1 - F_2 = 0$$

The total moment (force  $\times$  distance) acting about the left-hand support can be reckoned (see LEVER); if the centre of mass of the bridge is midway across the span, then

$$\frac{Wl}{2} - F_2l = 0$$

From these two equations the expected result can be established that

$$F_1 = F_2 = \frac{W}{2}$$

Thus the required force is equal to half the weight of the beam in this case.

In this simple calculation, no allowance is made for the fact that the bridge is to some extent flexible. On the contrary, the bridge is assumed to be rigid inasmuch as use is made of a characteristic length  $l$  which could be measured before the beam is lifted off the ground and placed on its supports. Obviously, if the bridge were made of rubber, the distance between the supports would be much less than the length of the unsupported span, so that mathematically the required length  $l$  would depend upon  $W$ .

Since it is reasonable to assume that the variation of  $l$  is too small to be of consequence, this structure is said to be statically determinate. The effect of static determinacy is to separate the mathematical problem of equilibrium from that of compatibility (see ELASTICITY: *Theory of Strain*). Assumptions of this sort account largely for the great importance of the statics of rigid bodies; it is not that the bodies are really rigid but that they may be assumed so for the purposes of calculation.

**The Statics of a Rigid Body.**—The conditions under which a body, supposed rigid, can remain at rest must next be considered in more detail. Expressed algebraically, the problem is the examination of equations (21) and (22) of the article MECHANICS, when all the time derivatives are 0. That is, for any rigid body at rest it is necessary to satisfy force equations

$$\left. \begin{aligned} F_x &= \sum f_x = 0 \\ F_y &= \sum f_y = 0 \\ F_z &= \sum f_z = 0 \end{aligned} \right\} \quad (1)$$

and also moment equations

$$\left. \begin{aligned} M_x &= \sum (xf_y - yf_x) = 0 \\ M_y &= \sum (yf_z - zf_y) = 0 \\ M_z &= \sum (zf_x - xf_z) = 0 \end{aligned} \right\} \quad (2)$$

In words, equation (1) states that the sums of the resolved parts of the external forces in the directions of fixed orthogonal axes OX, OY, and OZ shall be 0. The quantities  $M_x$ ,  $M_y$ ,  $M_z$  are the moments about OX, OY, and OZ of the external forces, and these also must vanish.

While equations (1) and (2) govern the forces acting on a body at rest, it is not necessarily possible to solve these equations explicitly. Statically determinate systems only are of concern here, so that this difficulty will not arise.

**Static Equivalence; Transmissibility.**—Suppose that a rigid body is under the action of forces, one of which is of magnitude  $f$  and is applied to it at some point P (fig. 2).

Let the component of  $f$  in the plane XOY be  $r$ ; it is obtained by projecting the force vector parallel to ZO. Now the state of rest of the body will not be altered if two equal and opposite forces  $f$  are applied at Q (as in fig. 2), Q being a point lying on the line of action of  $f$ . They too will have components  $r$  (see VECTOR ANALYSIS).

The effect on the equilibrium of the outer pair of these components  $r$  (dashed arrows in fig. [2B]) is nil, since they are equal and opposite and have no net moment about the axis OZ. If removed, these components leave only the one component  $r$  shown.

FIG. 2

Similar conclusions are reached by projecting the original forces at P and Q on to the planes YOZ and ZOX. If the three remaining components (of which  $r$  in fig. 2[B] is one) are now compounded, they give the force  $f$  at Q, as shown in fig. 2(B). The remaining force  $f$  at Q is statically equivalent to the original force  $f$  at P in that substitution of one for the other has no effect on the state of equilibrium of the body. To this extent, then, the point of application of  $f$  may be transmitted along the line of action; this is known as the property of transmissibility of a force.

**Parallel Forces and Couples.**—Consider two parallel forces which act on a body; their lines of action define a plane. The addition of these forces is clearly a case which cannot be dealt with by the parallelogram law of vectors, since the lines of action do not intersect (see FORCE).

A simple extension of the above reasoning shows that the statical effects of a given system of forces acting on a body are unaltered by the imposition of two equal and opposite forces having the same line of action.

If, therefore,  $f_1$  and  $f_2$  (shown in fig. 3) are two parallel forces (acting in the plane of the paper) whose resultant is required, the equal and opposite forces  $P$  can be superposed as shown. The resultant of  $P$  and  $f_1$  is  $R_1$  and that of  $P$  and  $f_2$  is  $R_2$ . Let the lines of action of  $R_1$  and  $R_2$  intersect at A; this point may be regarded as the point of application of  $R_1$  and  $R_2$  and hence of  $f_1$  and  $f_2$  without the forces  $P$ .

The forces  $R_1$  and  $R_2$ , supposed acting at A, may now be replaced by their components  $P$ -plus- $f_1$  and  $P$ -plus- $f_2$ , respectively. Since the forces  $P$  again neutralize each other, there is left the resultant force which is parallel to  $f_1$  and  $f_2$ , is of magnitude  $f_1 + f_2$  and acts through A. The position of the line of action of the resultant force may easily be deduced. For, by consideration of similar triangles (see SIMILAR FIGURES),

$$\frac{CB}{BA} = \frac{P}{f_1}; \quad \frac{BD}{BA} = \frac{P}{f_2}$$

It follows that

$$\frac{CB}{BD} = \frac{f_2}{f_1}$$

If the parallel forces  $f_1$  and  $f_2$  act in opposite directions, their resultant can be found by similar means. It will act in the plane of  $f_1$  and  $f_2$  and will be found to act outside the space between the lines of  $f_1$  and  $f_2$ . The magnitude of the resultant is then the difference between  $f_1$  and  $f_2$ , and its direction is that of the greater of the two.

The lines of action of  $R_1$  and  $R_2$  (which fix the point A in fig. 3) are parallel if  $f_1$  and  $f_2$  are equal in magnitude and opposite in direction, so that a single resultant force cannot be found. A pair of forces of this nature is said to constitute a couple, and the plane containing the constituent forces is the plane of the couple.

Suppose that a body could be found with all the forces acting on it in a single plane, say the plane XOY. If a couple acts on the body (fig. 4), then clearly the forces  $f$  make no net contribution to either of the relevant force equations (1); that is,

$$F_x = F_y = 0$$

The forces do, however, contribute to the relevant equation (2), namely,

$$M_z = 0$$

since they have a net moment about the axis OZ (perpendicular to the plane XOY). Their contribution is

$$[(f \times OD) - (f \times OC)] \text{ or } fl$$

FIG. 4

where OCD is perpendicular to the lines of action of the two forces  $f$ , and  $l$  is the distance between these lines.

The moment of the couple in this case is of magnitude  $fl$ . Evidently the two forces could be moved to act in the plane at any points of the body and in any direction in this plane without affecting the conditions of equilibrium. It is necessary only that the product of the magnitude of the forces and the distance between their lines of action should be kept equal to  $fl$ . In this problem, in which all forces act in one plane, a couple is completely defined by the magnitude and direction (clockwise or counter-clockwise) of its moment.

**Vectorial Nature of Couples.**—It has been shown that the effect of a couple on the equilibrium of a body is not altered if the couple is moved in its own plane. It is next shown that if the equilibrium exists, it is not disturbed if the plane of action of the couple is moved parallel to itself.

FIG. 5

Let a couple of moment  $fl$  act on a body in a plane A (fig. 5[A]). The equilibrium of the body will be unaffected if two pairs of equal forces  $f$  are applied with their lines of action distance  $l$  apart on a parallel plane B. Now the forces  $f'$  may be added, giving the resultant  $R'$ , while the forces  $f''$  give the resultant  $R''$ . And since  $R' = R''$ , these resultants neutralize each other and may therefore be removed without influencing the equilibrium. There remain only the two forces in plane B, which form a couple of moment  $fl$ .

The previous conclusions can now be extended to cover couples in space. It may be seen that a couple is completely defined by (1) the magnitude of its moment; (2) the orientation of the plane in which it acts; and (3) the sense in which it acts (thus the couple in fig. 5[A] acts in the clockwise sense when looking from plane A to plane B). It is evident that a couple can be represented by a line whose length represents its moment, whose direction is normal to the plane of the couple, and which points in a direction whose relation to the sense of the couple is that borne by the advancement to the rotation of a right-hand corkscrew. Under this convention, the couple of fig. 5(A) may be represented by the arrow in fig. 5(B).

Lines such as this are, in fact, vectors, since they permit couples to be added according to the parallelogram law. Suppose that two couples act on a body in different planes which intersect in a line containing two points C and D (fig. 6[A]). By movement in their own planes and movement of the type just described, the couples can be replaced by forces  $f_1$  and forces  $f_2$  whose lines of action are separated by the distance  $l$  between

FIG. 6

C and D; it is merely necessary, when finding  $f_1$  and  $f_2$ , that the moments of the couple be  $f_1 l$  and  $f_2 l$ .

The forces at C and D can be compounded in the usual way, giving the resultant forces  $R$ . Thus the sum of the two original couples is a couple of magnitude  $Rl$  whose plane is fixed by the vectors  $R$ . The planes containing the pairs of forces  $f_1$  and  $f_2$  and  $R$  are indicated in the figure.

Now the original couples can be represented by the lines of length  $f_1 l$  and  $f_2 l$  (fig. 6[B]) in accordance with the corkscrew rule, these lines being perpendicular to the planes containing the pairs of forces  $f_1$  and  $f_2$ , respectively. If these lines are now added by the parallelogram rule as shown, it can be seen that the construction is geometrically similar to those made before at C and D; the parallelogram is rotated through a right angle, and its sides are  $l$  times as long as the previous ones. The diagonal, therefore, correctly represents the resultant couple  $Rl$ .

If a body is acted upon by several couples, then these may be compounded by repeated use of the parallelogram rule or, just as with the forces acting on a particle, by means of a space polygon.

If the polygon closes, there is no resultant couple acting. Further, any couple may be resolved into components by the parallelogram rule.

**Static Equilibrium of a Rigid Body.**—The analytical conditions for equilibrium of a rigid body are those of equations (1) and (2), which will now be interpreted in terms of vectors.

Suppose that a force  $f$  is applied at some point A ( $x, y, z$ ) of a rigid body and consider its component  $f_x$  (fig. 7). This component of the force enters equations (1) and (2) through: (1) its contribution to  $F_x$ ; and (2) its contributions  $-yf_x$  to  $M_y$  and  $zf_x$  to  $M_z$ . If, therefore, the component  $f_x$  is replaced by a force of equal magnitude acting at O, together with the couples shown in the figure, the equilibrium of the body would not be influenced. If O lies outside the body, the force and couples may be imagined as being applied to an extension of the body which extends to the origin.

A similar argument may now be applied to the remaining components  $f_y$  and  $f_z$  of  $f$ . The force acting at A is therefore statically equivalent to a force passing through O (with components  $f_x, f_y$ , and  $f_z$ ) and a couple whose components in the directions OX, OY, and OZ, are  $(yf_z - zf_y)$ ,  $(zf_x - xf_z)$ , and  $(xf_y - yf_x)$ . The components of this couple are the contributions of  $f$  to  $M_x, M_y, M_z$ .

This force  $f$  may be regarded as typical of all the applied forces so that equations (1) and (2) can be regarded merely as statements that the sum of the components of these equivalent forces and couples must all be 0. In other words, there must be no resultant equivalent force acting at O and no resultant couple. The space polygons of the equivalent forces and couples must both close. Thus, except for no forces or the special case of two equal and opposite forces, the minimum number that can produce equilibrium is three forces.

Furthermore, an unbalanced couple can be balanced only by an equal couple with opposite sense.

**Centre of Gravity.**—The weight of a body is the external force exerted upon it by the gravitational attraction. It is the resultant of the contributions (to the total body force) of the separate gravity forces exerted upon the particles which may be thought of as forming the body.

The force on each particle is proportional to its mass, and the forces are assumed parallel; under these circumstances it may be shown that their resultant always passes through a particular point fixed in the body.

Referring again to fig. 7, let  $f_x$  be the component in the direction OX of the gravity force of one of the constituent particles. Now whatever the direction of the gravity forces on the various particles, their components in any direction will be proportional

to the masses of the particles. Let these components be

$$(f_x)_1 = km_1; (f_x)_2 = km_2; \dots$$

for the particles  $m_1, m_2, \dots$

It will now be seen by reference to fig. 7 that these various components could be replaced by a force

$$f_x = k \Sigma m = kM$$

directed along OX together with couples

$$\Sigma(-yf_x) = -k \Sigma my \text{ about OZ}$$

and

$$\Sigma zf_x = k \Sigma mz \text{ about OY}$$

Consider now a single force  $F_x$ , acting parallel to OX. Evidently it will be statically equivalent to all the components  $(f_x)_1, (f_x)_2, \dots$  etc., provided that its equivalent force and couples at O are the same as before. It is necessary that

$$F_x = kM; -F_x \bar{y} = -k \Sigma my; F_x \bar{z} = k \Sigma mz$$

where  $\bar{y}$  and  $\bar{z}$  are the distances of the line of action of  $F_x$  from the planes XOZ and XOY, respectively. It follows that

$$\bar{y} = \frac{\Sigma my}{M}; \bar{z} = \frac{\Sigma mz}{M}$$

In the same way the components of gravity force in the directions OY and OZ can be considered. It follows that a single force  $F$  having components  $F_x, F_y$ , and  $F_z$  can represent the sum of the various forces on the particles. Each component of  $F$  is equal to the sum of the corresponding components of the particle forces. Further it is necessary that  $F$  should act at the point  $(\bar{x}, \bar{y}, \bar{z})$  of the body. This point may sometimes be referred to as the centre of mass, but it is called the centre of gravity in the present context (see NAVAL ARCHITECTURE: *Weight and Buoyancy*). See also DYNAMICS.

**BIBLIOGRAPHY.**—A. P. McMullen and E. W. E. Kempson, *Elementary Experimental Statics for Schools* (1936), contains a very simple introduction to the subject; A. S. Ramsey, *Statics* (1941) is an elementary textbook with a mathematical flavour; S. P. Timoshenko and D. H. Young, *Statics*, 4th ed. (1956), introduces the subject of statics and emphasizes its engineering applications; E. J. Routh, *A Treatise on Analytical Statics*, 2 vol., 2nd ed. (1896–1902), deals with more advanced problems in statics. See also R. H. Goff and D. E. Hardenbergh, *Introduction to Statics* (1965). (R. E. D. B.)

**STATIONERY**, a word that now covers all writing materials and implements, together with the numerous appliances of the desk and of business offices. For the principal articles and operations of the stationery trade, see INK; OFFICE MACHINES AND APPLIANCES; PAPER MANUFACTURE; PEN; PENCIL.

**STATISTICAL MECHANICS**, also called statistical thermodynamics, is that branch of theoretical physics in which the measurable properties of macroscopic substances (whether solids, liquids, or gases) are related to or predicted from the attributes of the microscopic systems (atoms or molecules) of which these substances are composed. Since all substances obey the laws of thermodynamics, these laws themselves must emerge as a consequence of the molecular structure of matter, and it is by the success of the theory in justifying this supposition that the alternative designation is best vindicated. On the other hand, since the theory itself is basically a combination of mechanics and probability theory, or statistics, the phrase statistical mechanics, originating (1901) from the U.S. mathematical physicist J. Willard Gibbs (1839–1903), is perhaps more accurately descriptive of the subject.

Statistical mechanics, indeed, owes to Gibbs much more than its name. Its formal, mathematical structure for computational purposes is still, apart from the inevitable but comparatively minor changes introduced by the development of quantum mechanics, essentially that presented in Gibbs's *Elementary Principles in Statistical Mechanics* (1902). But much progress has since been made both in the application of this formalism to particular physical situations and in the understanding of its justification. Satisfactory agreement with experience had to

FIG. 7

await the creation of the quantum theory about 25 years later. Moreover, Gibbs himself produced the formal structure as a statistical model which obeyed or embodied the laws of thermodynamics without fully justifying this model on the basis of molecular behaviour. Judged pragmatically, Gibbs's formalism certainly provides the correct prescription for calculating equilibrium macroscopic properties from microscopic ones, but a complete justification of the procedure from the laws of molecular dynamics presented a difficult and only partially solved problem in the 1960s. Advances in the mathematical theory of probability, however, have done much to clarify the situation. For critical discussion of the foundations of statistical mechanics reference should be made to the books by R. C. Tolman, D. ter Haar, and especially A. I. Khinchin, listed in the bibliography at the end of this article.

The history of the subject properly starts, however, not with Gibbs, who by largely abandoning the details of molecular mechanics broke with tradition, but three or four decades earlier with the contributions by James Clerk Maxwell (1831–79) and Ludwig Boltzmann (1844–1906) to the kinetic theory of gases. Kinetic theory itself dates from the 18th century, though it was not until after the work of the English chemist John Dalton and the Italian physicist Amedeo Avogadro in the early 19th century that the concepts of atoms and molecules could be entertained seriously as physical realities. The laws of thermodynamics also are 19th-century discoveries (*see THERMODYNAMICS*).

Although the atomic hypothesis played its part in the overthrow of caloric theory (*see HEAT*), the laws of thermodynamics are purely phenomenological, making no reference to the ultimate constitution of matter. These laws are phrased in terms of concepts, some of which are peculiar to thermodynamics; of these temperature is the most familiar example. Others, such as the work done on a thermodynamic system by external agencies, relate directly to mechanics or to the energetics of electromagnetic theory. It is convenient at this point to summarize these laws, using modern notation and with a minimum of discussion. The account does not pretend to logical completeness and should be regarded solely as a brief recapitulation of phenomenological heat theory.

1. One may speak of thermal equilibrium between two systems; thus if two systems are each in thermal equilibrium with a third, then they are in thermal equilibrium with each other. This permits empirical temperature scales to be defined (*see THERMOMETRY*).

2. One may speak of an adiabatically enclosed (thermally insulated) system, and then the work required to change the system from one equilibrium state to another is independent of how this work is supplied. This allows internal energy ( $U$ ) to be defined apart from an additive constant.

3. No cyclic heat engine can simply extract internal energy from a system and convert it fully into useful mechanical work. This permits a logical introduction of the concepts entropy ( $S$ ) and absolute temperature ( $T$ ).  $S$ , like  $U$ , is defined apart from an additive constant, and  $T$  is arbitrary to the extent of a scale factor.

Statement 1, which underlies the whole science of thermometry, has been accepted as a matter of common experience since at least the time of Galileo, but its recognition as a basic phenomenological law of thermodynamics is comparatively recent. The descriptive phrase, the zeroth law, was coined by Sir Ralph Fowler.

The second statement constitutes the so-called first law of thermodynamics. When a system is not adiabatically enclosed the extra energy, apart from the work ( $\Delta W$ ) done on the system, required to produce the resulting change in internal energy ( $\Delta U$ ) is known as the heat supplied ( $\Delta Q$ ), so that

$$\Delta U = \Delta Q + \Delta W \quad (1)$$

The third statement summarizes the so-called second law of thermodynamics. Alternative statements (for example, that without compensating changes heat cannot flow from colder to hotter bodies), suitably interpreted, can be shown to be equivalent to it. For the purposes of this article, however, it suffices to con-

fine attention to the mathematical consequence of statement 3; i.e., for any small change from one equilibrium state to another the heat ( $\delta Q$ ) absorbed by a thermodynamic system may be written

$$\delta Q \leq T \delta S \quad (2)$$

where the equality holds only for a reversible or quasi static process. Thus for a spontaneous adiabatic process (for which  $\delta Q = 0$ ),  $\delta S$  is positive; i.e., the entropy of the system increases. It is important to appreciate that  $S$ , like  $U$  or  $T$ , is a thermodynamic property whose value is fixed when the state of the system is given. It is for this reason that the differential notation  $\delta S$  has been employed in equation (2).

The history of both the first and second laws of thermodynamics is complex. Suffice it to note that although the term entropy was first introduced by R. J. E. Clausius as late as 1865, the foundations for the understanding of this law had been laid by N. L. Sadi Carnot 40 years earlier. That heat is energy in transit (to use a modern phrase) was perhaps first convincingly demonstrated by J. P. Joule in the 1840s. Certainly by the 1850s both the first and second laws were fairly well established, Clausius and William Thomson, later Lord Kelvin, having played a chief part in clarifying the situation. It was Thomson who introduced the concept of absolute temperature, founding this directly on Carnot's earlier work.

It is to be emphasized, as was clearly appreciated by both Maxwell and Boltzmann, that this thermodynamic story is quite independent of any molecular picture of matter. Moreover, although energy is part of the mechanical description of things, temperature and entropy are concepts foreign to mechanics. Thus if a thermodynamic system (for example, a monatomic gas) is regarded as an assembly of enormously many atoms suffering mutual collisions (and perhaps with other forces between them, but essentially moving in accordance with the established laws of mechanics), it is proper to inquire what features of this mechanical situation are reflected or revealed in the thermodynamic concepts of temperature and entropy. Landmarks in the development of statistical mechanics are provided by Maxwell's work on the temperature problem (1859) and Boltzmann's on the entropy problem (1877). Although incomplete and partially faulty or obscure in their logic, these investigations effectively paved the way to modern statistical theory.

The link between the mechanical aspect of a system and its temperature, developed by Maxwell (and later [1868] by Boltzmann, too), is perhaps the most readily established link between mechanical and thermodynamic properties, though not the strongest. As will be seen, it did not fully withstand the transition from classical to quantum mechanics; and even had it done so its usefulness would inevitably have been somewhat limited. Nevertheless, its importance in the development of theoretical physics is immense; and where applicable it is still a useful working tool.

The connection is most simply established by considering the pressure exerted by a gas on the walls of its containing vessel. Mechanically this pressure represents the rate of dissipation, per unit area of the surface, of momentum directed at right angles to it. Clausius (1857) showed that if the atoms all had the same velocity  $v$  and moved in completely random directions then (there being  $N$  atoms each of mass  $m$ ) the pressure would be given by

$$pV = \frac{1}{3}Nm\overline{v^2} \quad (3)$$

where  $V$  is the volume of the container. Under the conditions of the derivation the gas is regarded as ideally dilute and so experimentally satisfies the equation of state

$$pV = nRT \quad (4)$$

where  $n$  is the amount of the gas in moles, and  $R$  is the so-called gas constant. Comparison of equations (3) and (4) yields

$$\frac{1}{2}m\overline{v^2} = \frac{3}{2}kT \quad (5)$$

where  $k = R/N_0$ . Here  $N_0$ , known as Avogadro's number, denotes the number of atoms per mole (in a monatomic substance); its numerical value is approximately  $6.02 \times 10^{23}$ .

That absolute temperature is thus a measure of the mean translational kinetic energy of the atoms of a gas was fully appreciated by Clausius (for the above argument barely depends on the assumption of equal velocities for all atoms); and Clausius also surmised that if the atoms or molecules were endowed with other forms of kinetic energy, e.g., rotational motion, then the kinetic energy of translational motion would simply constitute a definite proportion of the total kinetic energy of the molecular systems. It was, however, Maxwell who first derived the actual distribution of velocities among the systems of a gas. It also was Maxwell (though the theory owes much to Boltzmann) who gave precision and more than plausibility to this surmise of Clausius.

On the first point concerning the distribution of velocities among the atoms of a monatomic gas (or the molecules of a molecular gas) Maxwell used probability considerations to produce his celebrated formula

$$n(v) = N \frac{4a^3}{\pi^{\frac{1}{2}}} v^2 e^{-av^2} \quad (6)$$

where  $a$  is a parameter, and  $n(v)dv$  denotes the number of systems whose velocities lie in the interval  $v$  to  $v + dv$ . The factor  $4a^3/\pi^{\frac{1}{2}}$  ensures that all systems are taken into account; i.e., that

$$\int_0^\infty n(v)dv = N$$

If this distribution law is now used to find the mean translational kinetic energy of a system, it is found that

$$\frac{1}{2}m\bar{v^2} = \frac{m}{2} \int_0^\infty v^2 n(v)dv = 3m/(4a)$$

But by equation (5) this mean translational energy is  $\frac{3}{2}kT$ ; thus  $a = m/(2kT)$  and equation (6) may be written

$$n(v) = N \frac{4m^{\frac{3}{2}}}{\pi^{\frac{1}{2}}(2kT)^{\frac{3}{2}}} v^2 e^{-mv^2/(2kT)} \quad (7)$$

Maxwell's arguments leading to equation (6) are omitted here, partly for brevity and partly because the precise extent to which the laws of classical mechanics and probability theory imply this equation were not entirely clear in the 1960s. Yet there can be no doubt that equation (6) or (7) is, in fact, truly descriptive of the molecular state of affairs in a gas. There have been direct experimental verifications of this, also many indirect verifications. For example, since all directions of molecular motion are obviously equally probable, equation (7) may be rewritten

$$n(v_1, v_2, v_3) = \frac{N}{4\pi} \frac{4m^{\frac{3}{2}}}{\pi^{\frac{1}{2}}(2kT)^{\frac{3}{2}}} e^{-m(v_1^2 + v_2^2 + v_3^2)/(2kT)} \quad (8)$$

where now  $n(v_1, v_2, v_3) dv_1 dv_2 dv_3$  denotes the number of systems whose velocities in three mutually perpendicular directions lie respectively in the ranges  $v_1$  to  $v_1 + dv_1$ ,  $v_2$  to  $v_2 + dv_2$ , and  $v_3$  to  $v_3 + dv_3$ . Thus, if  $n_1(v_1)dv_1$  is the number whose velocity component in a given direction lies between  $v_1$  and  $v_1 + dv_1$  (regardless of any motion perpendicular to this direction), it is found on integrating over all values of  $v_2$  and  $v_3$  that

$$n_1(v_1) = \frac{mN}{(2\pi mkT)^{\frac{1}{2}}} e^{-mv_1^2/(2kT)} \quad (9)$$

This particular consequence of equation (7) can be directly tested in several ways. One way is through the Doppler effect on the wavelength of light emitted by a moving atom. This produces broadening of the spectral line (see SPECTROSCOPY) and gives it a characteristic profile that can be observed experimentally and also calculated very simply from equation (9). Indeed, equation (9) is so confidently accepted that it has been used since 1954 to infer from observed Doppler broadening the temperatures obtained in magnetically confined plasmas during attempts to achieve controlled thermonuclear reactions (see MAGNETOHYDRODYNAMICS).

Maxwell's second chief contribution to kinetic theory lay in his attempt to deduce from the laws of mechanics (combined inevitably with always rather fragile probability arguments) just how, if alternative forms of kinetic energy were available to the

systems of a gas, the total energy would be distributed among these forms. His work, and later that of Boltzmann, led to what is now known as the Maxwell-Boltzmann law of equipartition of energy. This asserts that when a system having  $s$  mechanical degrees of freedom is in thermal equilibrium at temperature  $T$ , then the expectation value of the kinetic energy associated with each degree of freedom is  $\frac{1}{2}kT$ , so that the total kinetic energy averaged over many such systems is  $\frac{1}{2}skT$  per system (see KINETIC THEORY OF MATTER).

A particularly simple illustration of this law is afforded by equation (5): a moving atom has three translational degrees of freedom. In general the number of degrees of freedom of a system is given by the number of coordinates required completely to specify its position in space and its internal configuration. For a diatomic molecule  $AB$  there are necessarily three positional coordinates (those of the mass centre), two angles are required to describe the orientation in space of the line  $AB$ , and the distance  $AB$  must also be regarded as variable. This would suggest that the internal energy of a diatomic gas is given by  $U = 3NkT$ , since  $s$  is now 6. Consequently the specific heat at constant volume  $C_v$  or  $(\partial U/\partial T)_v$  should be  $3R$  per mole for all diatomic gases, which is not the case. It is much closer to  $\frac{5}{2}R$  at ordinary temperatures but varies with temperature and is not the same for all such gases. For monatomic gases the specific heat  $C_v$  is indeed  $\frac{3}{2}R$  per mole, in agreement with the equipartition law.

Two other illustrations of the practical failure of the law warrant mention. Although derived from considerations relating to thermal equilibrium among the molecules of a gas, there would seem little reason that the law should not be applied equally to calculate the specific heat of a solid. In a monatomic solid each atom is in thermal equilibrium with the rest of the substance, and each atom has three degrees of freedom (corresponding to the three coordinates needed to specify its position in space). So it would be expected that the specific heat of a monatomic crystal like copper would be  $\frac{3}{2}R$  per mole. This is about half the room-temperature value. Now it is clear that in a solid the atoms do not move freely in space but vibrate about certain mean positions. They may indeed be supposed to execute simple harmonic motion about these mean positions under the influence of elastic restoring forces. In simple harmonic motion there is on the average as much potential as kinetic energy. Consequently, second thoughts demand twice as much internal energy per mole of crystal as that given by the kinetic energy alone, and a specific heat of  $3R$  per mole, in good agreement with many room-temperature values for appropriate solids. But this inclusion of an equal potential-energy term when vibrational motions are involved does not help to resolve, but indeed increases, the discrepancy in the case of diatomic gases. And, just as disastrously, the specific heats of solids are found experimentally to decline to zero at very low temperatures (see SOLID STATE PHYSICS: *Physical Properties of Solids: Principles Determining Physical Form*).

The second illustration comes from application of the law to thermal radiation (see BLACK BODY). Here concern is with thermal equilibrium among all the possible electromagnetic waves that can exist within an enclosure of volume  $V$ . The number of mutually independent excitations with frequency between  $\nu$  and  $\nu + d\nu$  can be shown to equal

$$\frac{8\pi V}{c^3} \nu^2 d\nu \quad (10)$$

where  $c$  is the velocity of light. Since these are harmonic vibrations, each contributes  $kT$  to the internal energy of the enclosure. Consequently, the total energy of black-body radiation per unit volume at temperature  $T$  is

$$\frac{8\pi kT}{c^3} \int \nu^2 d\nu \quad (11)$$

However, all frequencies from  $\nu = 0$  to  $\nu = \infty$  are possible, and the integral diverges at the upper limit (i.e., at high frequencies or short wavelengths). This, the so-called ultraviolet catastrophe, cannot be dismissed on the grounds that an infinite energy might be physically unobservable, since the formula also predicts an

infinite specific heat, and it certainly does not require infinite energy to change the temperature within a finite enclosed vacuum.

The earlier of these discrepancies were familiar to Maxwell and Boltzmann. The ultraviolet catastrophe, discovered by Lord Rayleigh in 1900, only dramatically emphasized the unsatisfactory state of statistical theory at that time. Nevertheless, it was not in statistical mechanics as such, but in classical mechanics itself, that the fault lay. These failures of the theory were directly instrumental in promoting the creation of quantum mechanics to replace classical mechanics in atomic situations (see MECHANICS; QUANTUM MECHANICS). Where classical mechanics is applicable, the law of equipartition of energy is valid. It can be used profitably, for example, to discuss the amplitude of the thermal torsional oscillations of a suspended galvanometer mirror.

Nevertheless, even were it always valid, the law of equipartition of energy could never provide a direct link between mechanics and thermodynamics; thus Boltzmann's work relating entropy to mechanical concepts will now be discussed.

The most striking property of entropy is that of increasing with time in spontaneous changes of a thermodynamic system. The clue to the mechanical interpretation of entropy was first afforded by Boltzmann's discovery (1872) of a feature of the mechanical description of a molecular assembly having a like property. For simplicity consider a monatomic gas that is not necessarily in an equilibrium state. Suppose that at a particular instant  $f(x, y, z, v_1, v_2, v_3) dx dy dz dv_1 dv_2 dv_3$  defines the number of atoms within the volume element  $dx dy dz$  whose velocity components lie in the ranges  $v_1$  to  $v_1 + dv_1$ ,  $v_2$  to  $v_2 + dv_2$ ,  $v_3$  to  $v_3 + dv_3$ . Boltzmann showed that the quantity  $H$  defined by

$$H = \int \dots \int f \ln f dx dy dz dv_1 dv_2 dv_3 \quad (12)$$

(where  $\ln$  stands for natural logarithm) never increases as the result of atomic collisions. More precisely, it remains constant if  $f(x, y, z, v_1, v_2, v_3) = n(v_1, v_2, v_3)/V$ , where  $n(v_1, v_2, v_3)$  is given by Maxwell's velocity distribution law, equation (8); otherwise it decreases. This result, Boltzmann's celebrated  $H$  theorem, was certainly not proved rigorously: statistical assumptions in the classification of collisions are certainly made, as Boltzmann came to realize; and these demand more justification than they received at that time. Nevertheless, the historical importance of Boltzmann's  $H$  theorem can hardly be overestimated, and for a critical discussion of its status, reference must be made to the appropriate works already cited, and listed in the bibliography below. More generally, for nonuniform molecular gases each molecule having  $s$  degrees of freedom requires  $s$  coordinates  $q_1, q_2, \dots, q_s$  to specify its positional state. In the language of analytical mechanics there are now  $s$  momenta  $p_1, p_2, \dots, p_s$  conjugate to these coordinates, and  $f(q_1, q_2, \dots, q_s, p_1, p_2, \dots, p_s) dq_1 \dots dq_s dp_1 \dots dp_s$  may be defined as the number of systems at any instant whose coordinates lie in the ranges  $q_1$  to  $q_1 + dq_1$ , etc., and whose momenta lie in the ranges  $p_1$  to  $p_1 + dp_1$ , etc. In place of equation (12), the quantity which as a result of molecular collisions is nonincreasing in time is now given by

$$H = \int \dots \int f \ln f dq_1 \dots dq_s dp_1 \dots dp_s \quad (13)$$

Boltzmann realized that  $H$  so defined behaves essentially as the negative of the entropy of the gas.

Boltzmann, however, went further than this. The conceptual space in which a coordinate system is provided by the  $2s$  quantities  $q_1, \dots, q_s, p_1, \dots, p_s$  is known in analytical mechanics as phase space (more precisely, it is the phase space appropriate to a single molecule of the gas); and Boltzmann (1877) imagined this phase space subdivided into a number of equal cells labeled  $1, 2, \dots, i, \dots, r$ , each of magnitude  $dq_1 \dots dq_s dp_1 \dots dp_s$ , equal to  $\tau$ . If now  $n_i$  denotes the number of molecules at a given instant such that their coordinates and momenta define a point within the  $i$ th cell in phase space then, on replacing the integral by a sum, equation (13) may be written

$$H = -(\sum_i n_i \ln n_i) \tau \quad (14)$$

Because concern is only with changes in  $H$ , just as only changes in entropy can be determined calorimetrically, and since  $\sum_i n_i = N$  is a fixed quantity, equation (14) may be modified to read

$$H = -\tau [\sum_i (n_i \ln n_i - n_i) - (N \ln N - N)] \quad (15)$$

or

$$H = -\tau \ln \frac{N!}{n_1! n_2! \dots n_r!} \quad (16)$$

In deriving equation (16) from equation (15) use is made of the approximation

$$\ln n! = n \ln n - n$$

which effectively holds mathematically for the logarithm of the factorial of a large number. It has therefore been assumed that all the distribution numbers  $n_1, n_2, \dots, n_r$  are large; i.e., that the cells in phase space provide only a rather crude description of the instantaneous dynamic state of the gas.

Now  $N!/(n_1! n_2! \dots n_r!)$  is simply the number of ways in which  $N$  molecules can be so distributed among the cells in phase space that the  $i$ th cell contains  $n_i$  of them; i.e.,  $n_i$  of them are in dynamic states corresponding to points in the  $i$ th cell. Boltzmann called this the number of complexions  $W$  pertaining to the set of distribution numbers  $n_1, n_2, \dots, n_r$ ; and equation (16) reads

$$H = -\tau \ln W$$

If  $H$  then is proportional to the negative of the entropy  $S$ , it follows that for a change in the state of the gas

$$S_2 - S_1 \text{ is proportional to } \ln W_2 - \ln W_1 \quad (17)$$

The more famous formula

$$S = k \ln W \quad (18)$$

is due not to Boltzmann but to Max Planck, but the constant  $k$ , later to be identified with the  $k$  of equation (5) above, is known as Boltzmann's constant. Its numerical value is about  $1.38 \times 10^{-16}$  ergs per degree. Unlike equation (17), equation (18) specifies a value for the entropy  $S$  and, therefore, necessarily exceeds thermodynamic requirements. The quantity  $W$  received the unfortunate name "thermodynamic probability"—it is neither a thermodynamic quantity nor a probability, being a large integer.

Boltzmann did, however, proceed to identify the state of maximum "thermodynamic probability" with the equilibrium state of the gas. It is known that for a given adiabatically enclosed system the entropy increases until an equilibrium state is reached. Consequently, the equilibrium state of the gas is expected to be describable by distribution numbers  $n_1, n_2, \dots, n_r$  which make  $W$  a maximum subject to the two restrictive conditions

$$\sum_i n_i = N \quad (19)$$

$$\sum_i n_i \epsilon_i = U \quad (20)$$

Here  $\epsilon_i$  is the energy appropriate to the  $i$ th cell in phase space; the first condition prescribes a closed thermodynamic system, and the second further specifies adiabatic enclosure. The mathematical problem of maximizing  $W$  subject to these restrictive conditions is straightforward, with the solution (in customary current notation)

$$n_i^* = N \lambda e^{\beta \epsilon_i} \quad (21)$$

The parameters  $\lambda$  and  $\beta$  are fixed by the conditions of equations (19) and (20).  $\lambda$  can be eliminated easily enough by using equation (19); but  $\beta$  demands a physical interpretation.

Returning to the thermodynamic equations (1) and (2) above, for two neighbouring equilibrium states of any thermodynamic system

$$TdS = dU - \delta W \quad (22)$$

and for a gas (or any homogeneous fluid)  $\delta W$  can be replaced

by  $-pdV$ . Consequently equation (22) may be written

$$dU = TdS - pdV \quad (23)$$

the basic equation of all equilibrium thermodynamics. From equation (23)

$$\left(\frac{\partial S}{\partial U}\right)_v = \frac{1}{T} \quad (24)$$

On the other hand, substituting from equation (21) into equation (18) gives

$$S = Nk \ln \sum_i e^{\beta \epsilon_i} - k\beta U \quad (25)$$

whence

$$\left(\frac{\partial S}{\partial U}\right)_v = -k\beta \quad (26)$$

even though  $\beta$  itself depends implicitly on  $U$  through equation (20). Comparison of equations (24) and (26) suggests that  $\beta$  has the physical significance of  $-1/(kT)$ , so that equation (21) may be written

$$n_i^* = N \lambda e^{-\epsilon_i/kT} \quad (27)$$

It may also be observed that equation (25) yields

$$A = -NkT \ln \sum_i e^{-\epsilon_i/kT} \quad (28)$$

where  $A$  is the thermodynamic quantity known as Helmholtz energy and defined as  $U - TS$ , so that from equation (23)

$$dA = -SdT - pdV \quad (29)$$

The above identification of  $\beta$  with  $-1/kT$  is not strictly in accordance with the rules of statistical mechanics, since there has been an appeal to thermodynamic formulas which should themselves follow from statistical theory. The identification is most properly made by considering the work done in slightly changing the volume of the gas and showing that this has the form  $dU + dS/k\beta$ . However, the present, shorter approach is not without its interest. In any case, the identification is what would have been expected from equation (7), since for translational motion  $\epsilon = \frac{1}{2}mv^2$ .

Equation (27), perhaps written in the form

$$\frac{n_i^*}{n_j^*} = \frac{e^{-\epsilon_i/kT}}{e^{-\epsilon_j/kT}} \quad (30)$$

is known as Boltzmann's distribution law. Maxwell's law is a particular case of it and indeed Maxwell himself came close to this generalization of his velocity distribution formula. Equation (28) is particularly basic to further developments.

The generalizations and rather different attitude introduced by Gibbs will be described in the language of the quantum theory; but first Boltzmann's results will be recapitulated in this new language. The rather arbitrary cells in phase space have effectively the magnitude  $h^3$ , where  $h$  is Planck's constant (about  $6.62 \times 10^{-27}$  erg sec.). More importantly, summation over cells is replaced by summation over allowed energy levels, so that equations (28) and (30) become

$$A = -NkT \ln \sum_i \omega_i e^{-\epsilon_i/kT} \quad (31)$$

and

$$\frac{n_i^*}{n_j^*} = \frac{\omega_i e^{-\epsilon_i/kT}}{\omega_j e^{-\epsilon_j/kT}} \quad (32)$$

where  $\omega$  is the quantum-mechanical degeneracy associated with the energy  $\epsilon$ ; i.e., the number of independent wave functions with this energy. In equation (32), the distribution numbers now refer to molecules having certain energies, rather than to certain cells in phase space. Since the energy levels themselves explicitly depend on the volume of the enclosure, it is clear that equation

(31) provides an expression for  $A$  as a function of  $V$  and  $T$  from which, by equation (29), all other equilibrium thermodynamic properties of the molecular assembly can be computed. The route from mechanical to thermodynamic properties is complete, at least for gases.

Boltzmann justified his  $H$  theorem by considering in detail the effects of molecular collisions, and in so doing had necessarily particularized assumptions about molecular interactions. Gibbs wished to free statistical mechanics from any such conceivably unrealistic suppositions. And at the same time he sought a formalism equally appropriate to solids or liquids as to gases. Instead of considering a gas as a statistical assembly of many molecules, he considered a statistical ensemble of very many replicas of the molecular assembly, whether the latter be gaseous, liquid, or solid. The individual members of this ensemble might have different total energies  $E_i$  and, in particular, Gibbs focused attention on a so-called canonical ensemble in which the number of assemblies with energy  $E_i$  is proportional to

$$\Omega_i e^{\beta E_i}$$

Here  $\beta$  is a parameter independent of  $E$ , and  $\Omega_i$  in quantum-mechanical language is the number of independent wave functions descriptive of a molecular assembly with energy  $E_i$ . He then assumed that the measurable properties of an actual physical molecular assembly would be given by averages over the corresponding canonical ensemble so that in particular

$$U = \sum_i E_i \Omega_i e^{\beta E_i} / \sum_i \Omega_i e^{\beta E_i} \quad (33)$$

The different members of a Gibbsian ensemble have, of course, no physical interactions with each other; classical mechanics, or the quantum theory, is invoked only to show that a canonical ensemble will remain a canonical ensemble as time proceeds, which is essential if such averages are to yield equilibrium thermodynamic properties.

The similarity between equation (33) and the equation of the Boltzmann theory

$$U = \sum_i \epsilon_i n_i^* = N \sum_i \epsilon_i \omega_i e^{-\epsilon_i/kT} / \sum_i \omega_i e^{-\epsilon_i/kT} \quad (34)$$

is self-evident, and it is not surprising that Gibbs succeeded in showing that the parameter  $\beta$  in a canonical distribution would reflect the physical features of reciprocal temperature. It can, of course, be identified with  $-1/kT$ . Gibbs showed, indeed, that quantities calculated as averages over canonical ensembles would obey all the laws of equilibrium thermodynamics, the Helmholtz energy of a molecular assembly being given by

$$A = -kT \ln \sum_i \Omega_i e^{-\epsilon_i/kT} \quad (35)$$

Applied to a gas, whose individual molecules may have energies  $\epsilon_1, \epsilon_2, \dots$ , with degeneracies  $\omega_1, \omega_2, \dots$ , equation (35) leads identically to equation (31) if

$$\Omega = \sum W(n_1, n_2, \dots) \quad (\text{allowed } n\text{'s})$$

where

$$\sum_i n_i = N, \quad \sum_i n_i \epsilon_i = E$$

and

$$W = \frac{N!}{n_1! n_2! \dots \omega_1^{n_1} \omega_2^{n_2} \dots} \quad (36)$$

And this, of course, is just the number of ways in which it would be expected that individual energies could be ascribed to the molecules of a gas whose total energy is given.

Gibbs thus brilliantly succeeded in producing a self-consistent statistical model embodying the laws of thermodynamics; at the same time providing a universal recipe for computing measurable, macroscopic, physical properties—equations of state, specific heats, and so on—from the dynamic description of any molecular assembly. This recipe or prescription certainly receives full a

posteriori justification. What he does not do is properly justify, a priori, the identification of physical measurements with ensemble averages. And here, as in the Maxwell-Boltzmann theory, the gaps in the logic have to be filled in by more recent developments in statistical mechanics which are beyond the scope of this article.

Equation (35) is the basic equation of statistical mechanics for computational purposes. The quantity  $\sum_i \Omega_i e^{-E_i/kT}$  is known as the partition function for the molecular assembly. If all the energy within the assembly may be regarded as shared among individual molecules—as in a sufficiently dilute gas, when intermolecular forces may be ignored—then, as has been shown

$$\sum_i \Omega_i e^{-E_i/kT} = \left( \sum_i \omega_i e^{-\epsilon_i/kT} \right)^N \quad (37)$$

The quantity  $\sum_i \omega_i e^{-\epsilon_i/kT}$  is then known as the partition function for a single molecule. In either case each separate term in the partition function measures the relative probability in an actual physical system at temperature  $T$  of the particular mechanical state to which it refers.

Equation (37) is simply a particular case of the important factorization property of partition functions. If, for precision, the molecules of a gas can have two completely independent sources of energy (for example, translational and rotational energies  $\epsilon'_i$  and  $\epsilon''_i$  with degeneracies  $\omega'_i$  and  $\omega''_i$ ) then

$$\sum_i \omega_i e^{-\epsilon_i/kT} = \left( \sum_i \omega'_i e^{-\epsilon'_i/kT} \right) \left( \sum_i \omega''_i e^{-\epsilon''_i/kT} \right)$$

since  $\epsilon_i = \epsilon'_i + \epsilon''_i$  and  $\omega_i = \omega'_i \omega''_i$ . It follows that each independent source of mechanical energy makes its own contribution to the Helmholtz energy of the assembly, and thence its own contribution to the internal energy  $U$ , given by  $-T^2 \partial(A/T)/\partial T$ , and to the specific heat  $C_v$ .

Returning to the language of classical mechanics, the partition function  $\sum_i \omega_i e^{-\epsilon_i/kT}$  has now to be replaced by the phase

integral

$$\frac{1}{h^3} \int \dots \int e^{-\epsilon(q_1, \dots, q_n, p_1, \dots, p_n)/kT} dq_1 \dots dq_n dp_1 \dots dp_n$$

where the energy is now expressed as a function of position in phase space. The factor  $1/h^3$ , where  $h$  is Planck's constant, ensures that the quantum-mechanical partition function and the classical phase integral have the same numerical value at high temperatures; i.e., when  $kT$  is large compared with the effective spacing between energy levels allowed by quantum mechanics.

For the translational motion of atomic or molecular systems in a gas, the statistically important energy levels are always very close together compared with  $kT$ , and the partition function for translational motion is given by

$$\frac{1}{h^3} \int \dots \int e^{-\frac{1}{2} m (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)/kT} dx dy dz dp_x dp_y dp_z \quad (38)$$

i.e.,

$$\left( \frac{2\pi mkT}{h^2} \right)^{\frac{3}{2}} V$$

Consequently (proceeding from  $A$  to  $U$ ) the contribution to the internal energy from the translational motion is  $\frac{3}{2} kT$  per molecule, in accordance with the equipartition law. Rotational motion can normally also be considered classically and, because the rotational energy is again a separable quadratic function of the relevant momenta, this motion also normally contributes the equipartition value to the internal energy of the gas. However, vibrational motion can seldom be discussed classically, the energy levels being too far apart; which accounts for the various failures of the equipartition law already instanced.

On substitution from equations (37) and (38) into equation (35) there is found for the Helmholtz free energy of a monatomic gas the expression

$$A = -\frac{3}{2} NkT \ln(2\pi mkT/h^2) - NkT \ln V \quad (39)$$

a result that cannot be correct. For, increasing  $V$  and  $N$  proportionately does not likewise increase  $A$ , although thermodynamically  $A$  is, of course, a simple extensive property of the gas. Gibbs realized this and suggested that the trouble arose from the indistinguishability of the  $N$  atoms of the gas. If only distinguishable complexions of the assembly were to be counted, then the above partition function for the gas ought to be divided by  $N!$  or alternatively in place of equation (36) there should be

$$W = \frac{\omega_1^{n_1} \omega_2^{n_2} \dots}{n_1! n_2! \dots} \quad (40)$$

Equation (39) now becomes

$$A = -\frac{3}{2} NkT \ln(2\pi mkT/h^2) - NkT \ln V + NkT \ln N - NkT \quad (41)$$

which is dimensionally correct. This is certainly the right procedure, but the indistinguishability of the systems of the gas has more profound quantum-mechanical effects than Gibbs was in a position to appreciate.

For simplicity let it be supposed that the translational energy levels are nondegenerate. Equation (40) then becomes

$$W = \frac{1}{n_1! n_2! \dots} \quad (42)$$

which, since the  $n$  values are integers, can hardly describe the number of ways of assigning energies to the systems of the gas in accordance with given distribution numbers. Indeed according to quantum theory

$$W = 1 \quad (43)$$

for when the single particle energies are known the state of the system is fixed.

With particles of atomic or molecular mass, equation (42) though strictly incorrect often (indeed usually) leads to right answers such as equation (41). The systems are then said to obey Maxwell-Boltzmann statistics. But equation (43) is necessary in dealing with substantially lighter particles such as electrons or photons (which have zero rest mass).

For electrons equation (43) and the conditions imposed by the Pauli exclusion principle,  $n_i = 0$  or  $1$ , must be invoked. The systems are said to obey Fermi-Dirac statistics, Enrico Fermi and Paul Dirac having independently deduced this consequence of quantum theory in 1926. A practical result is that the conduction electrons of a metal like copper do not, except at very low temperatures, contribute appreciably to the specific heat.

For photons or for helium atoms equation (43) suffices without further conditions on the  $n$  terms, a case of the use of Bose-Einstein statistics, the appropriate theory having been developed by Satyendra Nath Bose and by Albert Einstein in 1924.

The most important features of these specifically quantal statistics are summarized in the analogues of equation (21). For Fermi-Dirac statistics

$$n_i^* = \frac{\lambda e^{-\epsilon_i/kT}}{1 + \lambda e^{-\epsilon_i/kT}} \quad (44)$$

while for Bose-Einstein statistics

$$n_i^* = \frac{\lambda e^{-\epsilon_i/kT}}{1 - \lambda e^{-\epsilon_i/kT}} \quad (45)$$

The left-hand side of equation (44) or (45), as also of equation (21), must, of course, be interpreted as an average or expectation value; it is not necessarily an integer. In the particular case of photons or black-body radiation there is no restriction  $\sum_i n_i = N$ , since photons are not numerically conserved. This

has as consequence that  $\lambda = 1$  in equation (45). Since a photon of frequency  $\nu$  has energy  $h\nu$ , equations (45), (20), and (10) combine to give

$$U = \int_0^\infty \frac{8\pi V}{c^3} \frac{h\nu e^{-h\nu/kT}}{1 - e^{-h\nu/kT}} \nu^3 d\nu = \alpha VT^4 \quad (46)$$

where  $\alpha = 8\pi^5 k^4 / 15h^3 c^3$ .

Equation (46) was discovered semiempirically by Planck (1900) and historically marked the beginning of the quantum theory. Unlike equation (11), the integral in equation (46) does not diverge, and the integrand correctly reproduces the energy distribution in the frequency spectrum.

Except in the case of photons, the predictions of Fermi-Dirac and Bose-Einstein statistics coincide with those of Maxwell-Boltzmann statistics at sufficiently high temperatures; specifically whenever

$$\left(\frac{2\pi mkT}{h^2}\right)^{\frac{3}{2}} V \gg N$$

And this condition is certainly satisfied in practice for all atomic or molecular gases, with the possible exception of helium at very low temperatures.

This brief outline of the formal structure of statistical mechanics and of its historical origins could well end here. The calculation of transport coefficients, such as coefficients of viscosity or thermal conductivity, still requires detailed consideration of molecular collisions and is perhaps better regarded as part of the kinetic theory of gases than of statistical mechanics proper. However, a few more comments about the mechanistic interpretation of entropy may not be out of place.

Because the number of degrees of freedom of a macroscopic molecular aggregate is so large (of the order of  $10^{23}$ ) it can be shown that

$$\ln \sum \Omega_i e^{-E_i/kT}$$

can be replaced without loss by

$$\ln (\Omega^* e^{-E^*/kT})$$

where  $\Omega^* e^{-E^*/kT}$  is the greatest of the terms in the above sum; i.e., in the corresponding partition function. Consequently, by equation (35)

$$S = k \ln \Omega^* \quad (47)$$

where  $E^* = U$ . More properly this argument should invoke not a fixed energy but an infinitesimal energy range. Here, however, concern is not with mathematical rigour, and equation (47) must suffice. This is not precisely the same equation as Planck's equation (18), since all complexions for a given energy are now counted and not simply those corresponding to the most probable distribution numbers. Again, however, because fluctuations are macroscopically negligible, it is virtually equivalent to Planck's formula.

Now  $\Omega^*$ , or  $\ln \Omega^*$ , is a measure of what is not known about the dynamic state of an assembly if it is known only that it has total energy  $U$ . It is for this reason that entropy is sometimes said to measure our ignorance or uncertainty about the detailed dynamic state of the enormous number of microscopic systems (atoms or molecules) that together comprise the macroscopic systems of which there is direct physical experience.

**STATISTICAL ORGANIZATIONS, INTERNATIONAL.** The term international statistics refers to compilations of data on economic and social characteristics of peoples

and countries, drawn up in such a way as to permit intercountry comparisons. Such comparisons, to be of substantial validity, depend upon the application in each country of broadly uniform concepts, definitions and classifications to the subjects under investigation.

### EARLY HISTORY

**The International Statistical Congress.**—Efforts to develop uniform standards for international comparisons began in 1853 with the meeting in Brussels of the first International Statistical congress. The moving spirit of the first congress, and indeed of later ones, was Adolphe Quételet (1796–1874), a noted Belgian astronomer and one of the founders of scientific statistics. The congress held eight subsequent meetings between 1855 and 1876 in various European cities. The objective of the congresses was to agree upon and to seek to give effect to uniform practices for the compilation of national statistics in the interests of international comparability. Statisticians of more than 20 countries usually participated, including such distinguished persons as William Farr, Ernst Engel, Edward Jarvis and, of course, Quételet.

During this period it became clear that continuity between sessions was needed to advance the work more systematically and to avoid repetitious discussions. Various solutions were proposed, culminating in 1872 with agreement to establish a small permanent commission. In the course of the next few years the commission held four meetings and soon sought to become an authoritative institution to impose recommendations upon governments. This policy proved unacceptable; invitations to send representatives to another meeting of the commission in 1879 and to what would have been the tenth meeting of the International Statistical congress, in 1880, were refused by the German prime minister Bismarck and subsequently by the governments of several other European states. The scheduled meetings were not held, and the work of the congress and its permanent commission thereupon collapsed.

Despite the controversies that marked the end of the congress, its activities had given a strong impetus to the development of official statistics in Europe and to improvements in comparability. The congress had encouraged the compilation of internationally comparable tables, the most important of these being the publication in 1865 of *Statistique internationale de la population*, probably the first statistical publication compiled under international auspices, prepared by Quételet and Xavier Heuschling at the suggestion of the fourth congress (1860).

In addition, the congress was instrumental in encouraging the development of uniform standards. At the 1872 meeting, the congress agreed upon a list of items to be collected in population censuses. In 1853 initial work was done on what was to become the International Statistical Classification of Diseases, Injuries and Causes of Death.

**The International Statistical Institute.**—The dissolution of the congress by no means disposed of the then recognized need for international collaboration in statistics. International collaboration in a number of economic and social fields intensified the usefulness of statistical comparisons. These new developments, which led some statisticians to fear that statistics would become increasingly dispersed, together with the real need to continue the work of the International Statistical congress, led to the creation of the International Statistical institute (I.S.I.) in 1885.

The occasion was the jubilee meeting of the Statistical Society of London (since 1877 the Royal Statistical society) attended by about 40 foreign statisticians invited by the government of the United Kingdom. Unanimous agreement was reached upon proposals to create an international statistical organization that would avoid the difficulties encountered by the defunct congress. It was to be a private, scientific and unofficial body.

The I.S.I. held its first session in Rome in 1887 and met biennially until 1913 when World War I interrupted its meetings. During the period 1923 to 1938 it held ten sessions, its activities being once more interrupted by a world war. Members were elected in their personal capacities; many of them were official statisticians in their own countries.

The institute restricted its agenda to a smaller number of problems than had engaged the congress—a policy which resulted in more systematic work and in more carefully considered resolutions. The system of biennial meetings, while effective, could hardly keep pace with the rapidly expanding needs. A permanent office was established in 1913 to assist in the development of comparable methods, to assemble information from governments and to make arrangements for periodical publications. Special attention was given to demographic statistics. The first publication, in 1916, *Annuaire international de statistique*, was a compilation of the population statistics of European countries. Subsequent year-books covered other areas and other subjects. The *Annuaire* continued through 1921 and was superseded in 1922 by the *Aperçu de la démographie des divers pays du monde*, which appeared at intervals up to 1939, there being six issues in all.

In the meantime other international institutions were established. An international labour bureau was founded in Basel, Switz., in 1901. The International Institute of Agriculture (I.I.A.) was established in Rome in 1905, and in 1914 published the first issue of *Annuaire international de statistique agricole*. L'Office International d'Hygiène was organized in Paris in 1907, and in 1909 began to issue a monthly information bulletin, dealing, in part, with statistics on contagious diseases. An international conference on customs statistics, meeting in Brussels in 1910, laid the basis for an international convention, adopted in 1913, establishing the Bureau International de Statistique Commerciale, which was charged with compiling and publishing statistics on external trade in terms of a uniform commodity classification.

#### DEVELOPMENTS UP TO WORLD WAR II

**Problems of Organization.**—The outbreak of World War I naturally resulted in restriction or suspension of many of these developing activities. The end of the war brought new developments: the establishment in 1919 of the League of Nations and the International Labour Organization (ILO). The League and the I.S.I. were charged with broad responsibilities calling implicitly for the preparation of comparable statistics. Many of the then important subjects of official statistics had been taken up by one or another specialized organization, while the I.S.I. occupied a strong position of intellectual leadership, with a program actually or potentially embracing all fields of statistics. The newly created intergovernmental organizations could hardly divest themselves of responsibilities for compiling the statistics pertinent to their operations and for making recommendations to governments concerning these statistics. At the same time, the I.S.I. was loath to relinquish the position of leadership it had acquired over so many years.

During the next few years various schemes of collaboration were proposed and rejected. The I.S.I. and the League finally agreed on a system of mixed committees that prepared technical reports for submission to sessions of the I.S.I.: recommendations on external trade and fishery statistics were approved in 1923 at Brussels, on industrial (production) censuses in 1925 at Rome and on indexes of industrial activity in 1927 at Cairo.

**The International Convention.**—The recommendations of the I.S.I. were transmitted to the economic committee of the League, and when they were submitted for government comment, it appeared that several governments wished steps to be taken to give effect to the proposed standards. Accordingly, in 1927, the council of the League authorized the convening of a conference to prepare an international convention incorporating the recommendations. The International Conference Relating to Economic Statistics, meeting in Geneva in 1928, was attended by representatives of 42 states and drew up the International Convention Relating to Economic Statistics. This marked, up to that time, the high point in the development of international comparability.

The articles of the convention set out the type and frequency of statistics to be compiled on a wide range of economic subjects. It also established the Committee of Statistical Experts, which was charged with improving and amplifying the principles of the convention and advising on other classes of statistics in the inter-

ests of international uniformity. Certain classes of statistics—on agriculture, labour, transport and finance—were excluded from consideration because they fell within other jurisdictions. The committee was composed mainly of members of the I.S.I. serving in their personal capacities; arrangements were made for representatives of the ILO and the I.I.A. to participate in the work of the committee.

The Committee of Statistical Experts held eight meetings between 1931 and 1939 and made notable contributions to the improvement of comparability and to the development of statistics generally. The main accomplishments of the committee are contained in the series *Studies and Reports on Statistical Methods*, six of which were published by the League in 1938 and 1939 and the remaining three by the United Nations in 1947. Considerable attention was devoted to external trade statistics, the result of which was, among other things, the preparation of the Minimum List of Commodities for International Trade Statistics, designed to replace the Brussels classification referred to above. Other subjects covered by the methodological studies included statistics of the gainfully occupied population (an industrial classification), timber statistics, housing statistics, indexes of industrial production and statistics relating to capital formation. The committee also studied banking and balance of payments statistics. Reports on these latter subjects, and upon national income, were completed after the committee had ceased to function as a result of World War II.

**Other Statistical Organizations.**—During the period when the I.S.I. and the League were elaborating the principles that were to be contained in the convention, the ILO was active in preparing standards for labour statistics. This work was carried on principally by the International Conference of Labour Statisticians, the first meeting, in 1923, taking up the classification of occupation and industry, and statistics of wages, hours of work and industrial accidents. Later conferences discussed cost of living index numbers, unemployment statistics and real wages (1925); methods of family budget studies and statistics of collective agreements and industrial disputes (1926); and international comparison of real wages (1931). In 1933 the ILO established a committee of statistical experts to undertake preparatory work for the international conferences of labour statisticians and to advise upon problems of international comparisons of wages and the cost of living. The fifth conference (1937) prepared an international convention on statistics of wages and hours of work, signed in June 1938. The I.I.A. continued its work, especially the publication of a monthly bulletin and the *International Yearbook of Agricultural Statistics*, usually published biennially. While some hopes for more sophisticated agricultural statistics were never realized, much useful work was done, including the elaboration of the standards for agricultural and related statistics which were contained in the 1928 convention.

While the League and the I.S.I. were working out harmonious ways of collaboration, a somewhat different situation prevailed between l'Office International d'Hygiène Publique and the Health organization of the League. Agreement was finally reached whereby l'Office retained its independence, the Health organization was put on a permanent basis and the permanent committee of l'Office became the General Advisory Health council to the League although the League had its own health committee. The Health organization, among other subjects, took a strong interest in the International Statistical Classification of Diseases, Injuries and Causes of Death, a classification initiated at the first International Statistical congress in 1853 and finally adopted by the I.S.I. in 1893.

**Statistical Publications.**—Because of the controversy in the early 1920s between the I.S.I. and intergovernmental organizations, the statistical secretariat in the League was restricted to modest proportions. Nevertheless, in July 1921 the economic and financial section of the League assumed responsibility for the publication of the *Monthly Bulletin of Statistics*, which had been initiated in 1919 by the Supreme Economic Council of the Allied and Associated Powers. By 1927 it was possible to issue the *International Statistical Year-Book*, as a companion volume to the *Bulletin*, containing more subjects and more details. Subse-

quently, a number of specialized periodical publications were issued, many of them representing new departures in international statistics. The most important of these were: *Memorandum on Balances of Payments and Foreign Trade Balances* (1924) (later *International Trade Statistics*); *Memorandum on Production and Trade* (1926) (later *World Production and Prices*); and *International Trade in Certain Raw Materials and Foodstuffs by Countries of Origin and Destination* (1936-38). The *Network of World Trade*, published in 1942, became something of a classic in its analysis of trade relationships.

The ILO also began the publication of an increased quantity of labour statistics. From 1923 on, special articles appeared in the *International Labour Review*, and in 1936 the *Year-Book of Labour Statistics* appeared as an independent publication. The I.L.A. continued to publish a yearbook on agricultural statistics. Demographic statistics were published in the *Aperçu*, and health statistics mainly in the *Epidemiological Report* of the League's Health organization.

### WORLD WAR II AND AFTER

International statistical collaboration was virtually suspended during World War II. In June 1946, following the preparatory conference establishing the United Nations and the report of a temporary statistical commission, the United Nations Economic and Social Council (ESC) established a permanent Statistical commission of representatives of 12 (later 15) states to promote the development of national statistics and their comparability and to co-ordinate international statistical work generally. The Statistical office of the United Nations, as a central organ, was also established to collect, compile, analyze and publish statistics, to assist in statistical development and to maintain an international centre for statistics.

Two sessions of the commission were held in 1947 as it was considered necessary to organize the work as rapidly as possible. The commission met annually from 1948 to 1954, thereafter meeting biennially. The League's International convention, while remaining in force, was transferred by protocol to the ESC, which, advised by the Statistical commission, in effect replaced the Committee of Statistical Experts.

The fear, expressed by some observers, that a commission composed of governmental representatives instead of experts acting in their personal capacities would necessarily be ineffective proved groundless. With very rare exceptions, the members nominated by governments were the heads of their national statistical services and commanded international prestige. The fact that these representatives can assist directly to give effect to the recommendations of the commission in their own countries is an important advantage. The technical recommendations of the commission are not mandatory; they depend for their acceptance upon their cogency and applicability.

The problem of co-ordination also required immediate attention. The commission drew up the terms of a standard agreement covering statistical relationships between the UN and each of the specialized agencies. In general, the statistical activities appropriate to the special sphere of each agency were reserved to it.

**Secretariat Activities.**—In the meantime the normal secretariat duties of collection and publication of statistics were resumed or expanded. The Statistical office of the UN took over the publication of the *Monthly Bulletin of Statistics* with the Jan. 1947 issue, thus continuing without interruption the publication which during the latter part of the war had been published by the League both in Geneva and in Princeton, N.J. Arrangements were made to compile the *Statistical Yearbook*, which resumed publication in 1949. A new publication, the *Demographic Yearbook*, also appeared in 1949. The statistical services of other international agencies commenced publication of current and annual statistics: the International Monetary fund (IMF) initiated the monthly *International Financial Statistics* (1948) and the *Balance of Payments Yearbook* (1949). The Food and Agriculture organization (FAO) continued the *Yearbook of Food and Agricultural Statistics*, issued additional yearbooks on forest products and fisheries

(1947) and began publication of the *Monthly Bulletin of Agricultural Economics and Statistics* (1948). The ILO maintained and expanded the *Year Book of Labour Statistics* and the *Statistical Supplement of the International Labour Review*. In accordance with the agreements, each agency compiles the statistics relevant to its field and supplies them to any other agency upon request. Thus, labour statistics contained in UN publications are provided by ILO, and the UN provides statistics on population, trade, national income and the other subjects within its sphere. In 1963 the United Nations Educational, Scientific, and Cultural Organization (UNESCO) began publication of the *UNESCO Statistical Yearbook*.

The *List of Statistical Series Collected by International Organizations*, issued from time to time by the UN Statistical office, gives the sources of the series together with the titles of the international statistical publications.

Taken together, these developments resulted in a world-wide statistical system characterized by the full exchange of statistics and information among international agencies, by extensive consultation on technical questions and by active collaboration of national statistical services upon which international agencies must depend for statistics and for advice and assistance in the formulation of statistical standards. This latter function continues to be one of the most important and takes up a major part of the time of the various statistical services and of the Statistical commission itself.

Among the standards that have been developed by the UN and the specialized agencies through international consultations are: classification of international trade, classification of economic activities, occupational classification and various classifications and definitions applicable to censuses of population, housing, agriculture and industrial production and distribution. Principles have been established for the compilation of vital statistics, index numbers of industrial production, balance of payments, statistical sampling and other important economic and social subjects.

It has long been recognized that the divergent economic, social and political institutions in different countries and regions of the world require differentiated standards, so that absolutely uniform systems are not necessarily applicable from one country to another. Nevertheless, there are many common elements that find broad application in all countries and additional elements that may be applied on a regional or a community of interest basis. This situation has led to the development of regional groups for discussion of common statistical principles. The UN has established arrangements in Europe, Asia and Africa for periodic conferences and working parties to develop standard methods that are based on international standards but that are adapted to regional conditions.

The Inter-American Statistical Institute (1940), in co-operation with the UN, serves as a forum for the Americas. Other arrangements of this kind are of long standing: the Scandinavian countries met to discuss statistical matters as early as 1888, and the first conference of statisticians of the British Commonwealth and empire was held in 1920.

Complete lists of applicable international standards are issued by the Statistical office from time to time in the *Directory of International Standards for Statistics*. Standard definitions and methods for many of the important economic and social subjects have been prepared, and work continues under way in many other subjects. Existing standards must be reviewed periodically to evaluate their continued applicability; new problems and concepts constantly emerge requiring statistical treatment. For example, increasing attention has been given to input-output studies, to money-flow analysis, to conditions and levels of living and to the refinement of national accounting and price-index techniques.

**STATISTICS** was a term first applied to such data of importance to the political state as population, yield of taxation, value of trade, and mortality (see **CENSUS**); and to the study and interpretation of such data. As commonly understood nowadays, statistics is a mathematical discipline concerned with the study of masses of numerical data of any kind. See also **ECONOMETRICS**; **INDEX NUMBERS**; **BIOMETRY**; **STATISTICAL MECHANICS**.

### DESCRIPTIVE STATISTICS

**Statistical Tables.**—A simple way of arranging numerical data is to set them in tabular form. With knowledge of the amount of sugar consumed in a given country in each year of a given period, for example, a table may be drawn up as indicated by the headings below:

*Consumption of Sugar*

(1) Year	(2) Total consumption thousand lb.	(3) Population thousands	(4) Consumption per head, lb.
-------------	--	--------------------------------	-------------------------------------

Tabular arrangements of statistical data are found throughout these volumes; for example, see **OLYMPIC GAMES**; **DEBT, PUBLIC**. A detailed discussion of tabular material is given under **MATHEMATICAL TABLES**.

**Graphs.**—It is frequently useful to represent tabular data graphically. A number of examples of such graphs may be found in the articles **PRICES**, **STATISTICS OF**; **LIFE EXPECTANCY**.

Discrete variables comprise clear-cut classes; e.g., in a group of men and women, the sex variable has two distinct categories. A bar graph (separate bars drawn to different heights showing the number in each category) can represent discrete data. A continuous variable can change along a continuum (e.g., weight or I.Q. in a group of men). It may be graphed by a relatively smooth curve (frequency polygon) that changes in height to reflect the number of cases at different points on the continuum.

Even though graphs fall short of numerical tables in precision, they have the advantage of allowing a large mass of figures to be grasped as a whole much more readily than is possible when those figures are presented in one or more tables (see **GRAPH**).

**Averages and Dispersion.**—An illustration of a type of statistical table known as a frequency distribution is seen in the following summary of the heights of a number of men:

Height in inches . . . .	61	62	63	64	65	66	67
Frequency . . . . .	2	10	11	38	37	73	106
Height in inches . . . .	68	69	70	71	72	73	74
Frequency . . . . .	126	109	87	75	23	9	4

The table indicates that 126 men were found to be between 5 ft. 7½ in. and 5 ft. 8½ in. and similarly for other heights. In tables such as this some method of dealing with cases falling exactly on the dividing line between two adjacent intervals must be laid down, and a common method is to assign half the number found on the dividing line to each of the classes of which it forms the limit. This procedure may, of course, result in frequencies in some of the intervals which are not integers. The accurate average height of the 730 men covered by the table can be ascertained only by reference to a more detailed statement showing the height of each man exactly, instead of in a number of groups. It will be observed that 297 were not taller than 5 ft. 7½ in., while 307 were 5 ft. 8½ in. or more, the distribution being not quite symmetrical on both sides of the numerically largest group. The approximate average height was about 5 ft. 8 in. (see **MEAN**).

A table of this kind indicates more than the average height of the individuals represented. Note that 191 were not more than 5 ft. 6½ in. in height and 198 were not less than 5 ft. 9½ in. in height.

By calculation from the figures shown, assuming that the individual heights were distributed with approximate regularity along the intervals from inch to inch, the points representing 5 ft. 6.3 in. and 5 ft. 9.7 in. would divide the series of heights so that one-quarter of the whole number fell below the former, and one-quarter of the whole number above the latter. A similar calculation gives, as the point dividing the series into two equally numerous groups, 5 ft. 8.04 in. This last point is called the median (*q.v.*) of the series, and the two others are the lower and upper quartiles, the three points serving to divide the whole number examined into four groups of equal numbers of cases. The distance between the upper and lower quartiles, in the case in question 3.4 in., gives the range within which the middle half of the instances recorded lay. This distance (a measure of dispersion called the interquartile range) expresses much more definitely the degree of concentration of the individuals in the neighbourhood of the median height than, for example, the whole range (14 in.) within which all the measurements lie. If a more exact description of the nature of the distribution than is afforded by the specification of the median and quartiles, but of the same general character, is desired, the group may be divided into a number of parts, e.g., into ten equally numerous parts, the points of division being then known as deciles. Points of division called centiles (percentiles) divide the group into 100 equal parts (see **PERCENTAGE**). For the most commonly used measure of dispersion (*i.e.*, variability or spread within a frequency distribution) see **STANDARD DEVIATION**.

In many statistical problems the form of the distribution is of a recognizably definite character. It is found that, in numerous cases, the manner in which the individual observations are distributed is in close accordance with that of events dependent on chance. Such a case is presented by the following. A number of balls, indistinguishable in size, weight, or form, are placed in a bag, half of the balls being white and half black. If one ball be drawn from the bag, its colour, whether white or black, may be noted. The ball being replaced and the bag shaken, another drawing will give a result wholly independent of the first.

If a large number of sequences of  $x_r$  white (or of  $x_r$  black) balls are recorded on  $Y_r$  occasions, the total number  $n$  of drawings will be expressed by  $n = x_1Y_1 + x_2Y_2 + x_3Y_3 + \dots + x_rY_r + \dots$ . The relative frequencies of the different series are  $y_1, y_2$ , etc., where  $n \cdot y_1 = Y_1$ ,  $n \cdot y_2 = Y_2$ , etc., and, when  $n$  is indefinitely increased, the relation between the  $x$  and  $y$  values is represented by what is known as the normal probability curve, sometimes called the Gaussian curve or normal distribution (see **PROBABILITY**, **MATHEMATICAL**).

In any actual series of observations (e.g., of the colours of balls drawn from a bag) the observed numbers expressing the frequency of different events will be found to differ more or less from those expressed by the normal curve. Prolonged trials would give results approximating to those derived from theoretical calculations and expressed in the shape of the probability curve. Thus, in the case of the heights of 730 men, it is probable that records covering larger numbers of men, of the same race and social condition and within the same limits of age as those from which the 730 were selected, would give a distribution of heights more closely corresponding to that shown by a typical probability curve than the numbers cited. This Gaussian (normal) distribution is illustrated and discussed in greater detail under **ERRORS**, **THEORY OF**.

**Skew Distributions.**—Particular statistical problems yield distributions that are not symmetrical on either side of their mean (as compared with the symmetrical normal probability curve). These are said to be skewed: *i.e.*, grouped more closely on one side of the mean than on the other. The following distribution of weights of men shows marked skewness.

Weight in lb. . . . .	105	120	135	150	165	180	195	210
Frequency . . . . .	17	722	2,175	1,346	485	155	33	3

In this case the average (or arithmetic mean) of the weights of the 4,936 men is, on the assumption of continuous distribution, approximately 141.6 lb. The median is at about 140.5 lb. In the previous illustration of heights, the median was greater than the

mean, so that the skewness shown is of opposite direction in the two cases. If the mean is the greater of the two measures, the distribution is said to be positively skewed, or skewed to the right. When the median is the greater of these two measures of central tendency, the distribution is negatively skewed, or skewed to the left.

This illustration serves also to show a third measure of central tendency called the mode. The group of which 135 lb. is the central point is notably more numerous than any other. The weight 135 lb. may be called, as far as the figures furnish a ready indication, the most generally occurring weight or the modal weight. The point in the distribution thus determined is called the mode. A table like this, however, gives only a crude estimate of the most prevalent (modal) weight.

If the data in the table of weights had been less roughly grouped, the mode could be more accurately estimated. In a skew distribution the mode is related to the other two measures of central tendency as follows: it is lower than the arithmetic mean and the median in positive skewness; and is higher than these two in negative skewness.

**Three Variable Elements.**—In what precedes, the statistical material considered has consisted of series of pairs of quantities, the values of the two quantities in each pair being related; for example, where one of the quantities is the height of a man, the other the relative frequency with which men of that height were observed (see FUNCTION). Now consider series of three quantities, for example, where two of the quantities express the measures of different phenomena (which may be connected in some way, or may be independent) and the third expresses the relative frequency with which any combination of the other two occurs. Such a series is represented in the table given below, which shows how 1,000 marriages were distributed according to the ages of brides and bridegrooms.

Ages of wives at date of marriage	Ages of husbands at date of marriage						Total wives
	Under 25	25-34	35-44	45-54	55-64	65 and over	
Under 25	10	75	46	13	3	..	147
25-34	20	175	167	65	17	3	447
35-44	5	54	104	79	29	7	278
45-54	..	5	18	36	33	9	101
55-64	..	..	1	5	13	5	24
65 and over	..	..	..	..	1	2	3
Total husbands	35	309	336	198	96	26	1,000

It is clear, from the clustering of frequencies in a band crossing the table from its upper left side toward its lower right side, that there is some association (correlation) between the ages of the wives and husbands, old women tending to marry old men, and young women tending to marry young men. (A. W. F.)

**Correlation.**—Variables that tend to change together systematically are said to be correlated. If their values tend to rise and fall together the variables are positively correlated. Thus, from the table, age of husband is positively correlated with age of wife. If the value of one variable tends to fall as the other rises, the two are negatively correlated. For example, consider a boy at one end of a balanced plank (seesaw), and a girl at the other end. As the boy rises, the girl falls; and vice versa. Thus the elevation of the boy is negatively correlated with the elevation of the girl. Variables that change together in a completely random fashion are said to exhibit zero correlation. The weights of 100 pairs of soldiers selected at random (see RANDOMIZATION) from an infantry regiment would be expected to show zero correlation.

If each value of one variable exactly specifies one associated value for its correlated variable, the two variables are said to be perfectly correlated. In the example of the seesaw, the two elevation variables are perfectly correlated since the position of one child always specifies that of the other. The age correlation among marital partners is less than perfect, since any group of men of the same age tend to have wives who span a range of ages. Note from the table that husbands 65 and over have wives whose ages range all the way down to the 25-34 interval. This is an example of what is called regression: extreme values on one variable  $X$  tend to be associated with a range of values on the other,  $Y$ .

The arithmetic mean of this  $Y$  range tends to be less extreme (to regress, or fall toward the  $Y$  average). In perfect correlation there is zero regression, since each  $X$  value exactly specifies one  $Y$  value; there is complete regression in zero correlation, each  $X$  value being associated with a range of  $Y$  values whose arithmetic mean is the same as the mean for all  $Y$  values combined.

Correlation can be quantified with a number (correlation coefficient) that ranges from +1.00 (perfect positive), through 0.00 (completely random), to -1.00 (perfect negative). The algebraic sign indicates only the direction (positive or negative) of correlation. Degree of relationship is shown by the absolute size of the coefficient. Thus a correlation coefficient of +.50 shows the same degree of relationship as does one of -.50.

Suppose five people A, B, C, D, E are measured on variables  $X, Y$  to yield the following:

Individual	$X$ Score	$Y$ Score
A	60	83
B	55	109
C	40	121
D	20	126
E	10	130

Note that these data represent a perfect negative correlation (-1.00), since A scored highest on  $X$ , lowest on  $Y$ ; B next highest on  $X$ , next lowest on  $Y$ ; and so on.

One way to express this quantitatively is to calculate a Spearman rank-order correlation coefficient  $\rho_{XY}$  based on

$$\rho_{XY} = 1 - \frac{6\sum D^2}{N(N^2 - 1)}$$

where  $D$  is the difference between each pair of scores (each score expressed in rank form),  $N$  is the number of individuals (in this case 5), and  $\sum D^2$  is the sum of squared differences. Thus, assigning rank 1 to the highest score in each array, rank 2 to the next highest, and so on, the initial calculations are

Individual	Rank $X$	Rank $Y$	$D$	$D^2$
A	1	5	-4	16
B	2	4	-2	4
C	3	3	0	0
D	4	2	2	4
E	5	1	4	16
				40 = $\sum D^2$

Substitute appropriately in the equation and the correlation between  $X$  and  $Y$  is  $\rho_{XY} = 1 - [6 \times 40 / 5(25 - 1)] = -1.00$ ; a perfect negative correlation as expected.

Alternately the degree of relationship may be quantitatively estimated as a Pearson product-moment correlation coefficient  $r_{XY}$  calculated from

$$r_{XY} = \frac{\sum xy}{\sqrt{\sum x^2 \cdot \sum y^2}}$$

where  $x$  is the difference between each value of  $X$  and the arithmetic mean  $M_X$  of all  $X$  values (i.e.,  $x = X - M_X$ ); and  $y = Y - M_Y$ . Thus  $r_{XY}$  considers the actual values  $X, Y$  while  $\rho_{XY}$  considers only their ranks.

Both  $\rho$  and  $r$  can be used only with continuous variables (e.g., height  $v$ . weight, gas pressure  $v$ . temperature); for such discontinuous (discrete) variables as sex (male  $v$ . female), marital status (married  $v$ . not married), employment status (employed  $v$ . unemployed), other methods for calculating correlation coefficients must be sought. Among these special methods (only mentioned here) are the biserial, point-biserial, tetrachoric, and phi correlation coefficients.

The Pearson  $r$  will underestimate the degree of relationship when  $X$  and  $Y$  fail to change together in a linear (straight-line) fashion; i.e., when they fail to show linear regression. This may be observed by constructing what is called a scatterplot, representing each pair of values  $X, Y$  as a point in rectangular Cartesian coordinates. If the scatterplot shows a curvilinear relationship between  $X$  and  $Y$ , the Spearman  $\rho$  may be substituted. However, if the curvilinearity is so marked that the slope of the scatterplot reverses direction (tends to become parabolic),  $\rho$  will also under-

estimate the degree of relationship, and the so-called eta coefficient (only mentioned here) should be used. Such parabolic scatter-plots are sometimes encountered in industry, where employees on simple routines tend to produce best if they are of middle-range intelligence, those who are extremely dull or bright tending to do poorly.

To interpret the meaning of correlation coefficients it is helpful to think of them as expressing the degree to which variables  $X, Y$  exhibit variation in common. Such variation is usually given as the variance (i.e., the square of the standard deviation) for each variable. If all assumptions underlying the accurate use of  $r$  are met, then an  $r_{XY}$  of either  $+1.00$  or  $-1.00$  means that  $X$  accounts for all of the  $Y$  variance; it is then said that  $X$  and  $Y$  show 100% variance overlap, or that  $Y$  explains 100% of the  $X$  variance. However, an  $r$  of  $\pm .90$  does not represent 90% overlap; instead, it indicates 81% common variance. In other words, variance overlap is a function of the square of the correlation coefficient:  $r = \pm .80$  signifies 64% common variance;  $\pm .70$  represents 49% overlap; and so on.

For example, in estimating the effectiveness (validity) of intelligence test scores in predicting academic grades, it is common to compute the correlation coefficient between test scores and grades for different samples of students (see *PSYCHOLOGICAL TESTS AND MEASUREMENTS*). A typical validity coefficient from such studies is  $+ .60$ . In terms of overlap the test is then said to explain 36% of the variance in academic grades, 64% of the variance remaining unexplained. (C. C.E.)

### STATISTICAL INFERENCE

Thus far the discussion has been concerned with descriptive statistics: methods for succinctly describing masses of numerical data. Statistical inference deals with techniques used to assess the probable characteristics of masses of data when these data are incompletely known. For example, such methods are used to infer the probable average height of a large human population (or universe) on the basis of measurements taken from a sample of people derived from the universe. An understanding of *STATISTICS, MATHEMATICAL* should be helpful in understanding what follows.

**Statistical Tests.**—A statistical test is a procedure for testing a given hypothesis about the distribution law of a population from which a sample is assumed to have been drawn. The hypothesis in its simplest form is whether the cumulative distribution function of the population is some specific function  $F_1(x)$  alternative to a specified function  $F_0(x)$ . It is assumed that the sample comes from one of these populations. To test the hypothesis, a function  $u(x_1, x_2, \dots, x_n)$  of the sample  $x$  values is constructed, and a range  $R$  of critical values of this function is found so that the probability is a given value  $\delta$  (usually .01 or .05) of  $u(x_1, x_2, \dots, x_n)$  lying in  $R$  if the population cumulative distribution function is  $F_0(x)$ , and also such that the probability of  $u(x_1, x_2, \dots, x_n)$  falling in  $R$  when the population distribution  $F_1(x)$  is made as large as possible—certainly larger than  $\delta$ . Then the claim can be made that the sample has been drawn from the population having distribution  $F_1(x)$  with a risk of probability  $\delta$  of making a type-I error. By a type-I error is meant the error committed by saying that the sample is not from the population having distribution  $F_0(x)$ , when, in fact, it is. In other words, when the value of  $u(x_1, x_2, \dots, x_n)$  falls in  $R$  there is a risk of erroneously claiming the sample not to have come from the population with distribution  $F_0(x)$  when it actually does come from such a population. If the value of  $u(x_1, x_2, \dots, x_n)$  does not fall in range  $R$  the test calls for the assertion that the sample comes from the population having distribution  $F_0(x)$ , which is considered as the only alternative to  $F_1(x)$  at present. There is a risk of being in error in this assertion, too, because the sample could have come from the population with distribution  $F_1(x)$ . The probability  $\epsilon$  of this error is obtained by finding the probability of  $u(x_1, x_2, \dots, x_n)$  not falling in range  $R$ , when the sample has actually been drawn from the population having distribution  $F_1(x)$ . This error is called a type-II error. The probability of  $u(x_1, x_2, \dots, x_n)$  falling in  $R$  when the sample is from

the population having distribution  $F_1(x)$  is  $1 - \epsilon$  and is called the power of the test based on  $u(x_1, x_2, \dots, x_n)$ . When  $u(x_1, x_2, \dots, x_n)$  falls in  $R$  it is often said to be statistically significant at the  $\delta$  probability level. Usually,  $F_1(x)$  is a member of a family of functions  $F(x, \theta)$ , when  $\theta$  is a parameter, which would be a specific member of the family, say  $F(x, \theta_0)$ . In this case the power  $1 - \epsilon$  for the various alternatives corresponding to all values of  $\theta$  (except  $\theta_0$ ) would depend on  $\theta$  and is called the power function of the test based on  $u(x_1, x_2, \dots, x_n)$ . The essential idea underlying type-I and type-II errors was originally introduced by Bell Telephone Laboratories' quality control engineers who first referred to them in their own applications as producer's risk and consumer's risk, respectively. The producer's risk is the probability that a given lot of products of satisfactory quality offered by a producer will be rejected on basis of the results of an inspected sample from the lot, whereas the consumer's risk is the probability of the consumer's accepting a lot of products of unsatisfactory quality on basis of the results of the inspected sample. J. Neyman and E. S. Pearson (1928) developed the idea that underlies these two risks into the present theory of testing statistical hypotheses. Contributions to this theory and its application to various problems are numerous. Two important examples will be briefly discussed.

A. Wald (1950) further generalized the ideas by developing a theory of statistical decision functions in which decisions regarding a statistical hypothesis may be more numerous than simply acceptance or rejection and where the risks associated with such decisions are measured.

**The Student  $t$ -Test.**—Consider a sample of  $n$  items taken from a normally distributed population to test whether this population has a given mean  $\mu_0$ . Each measurement based on one case within the sample is signified by  $x_i$ . The criterion for this  $t$ -ratio test is

$$\frac{\sqrt{n}(\bar{x} - \mu_0)}{s} = t$$

where  $\bar{x}$  is the sample mean, and  $s^2$  is the sample variance

$$\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2$$

The sampling distribution of  $t$  when the sample has been drawn from a normal population with mean  $\mu_0$  is

$$dF(t) = \frac{\Gamma\left(\frac{n}{2}\right)}{\Gamma\left(\frac{n-1}{2}\right) \sqrt{\pi(n-1)}} \left(1 + \frac{t^2}{n-1}\right)^{-\frac{n}{2}} dt \quad (1)$$

where  $\Gamma(m)$  is the gamma function which equals  $(m-1)!$  if  $m$  is a positive integer and provides a good interpolation function for  $(m-1)!$  if  $m$  is real but not a positive integer. In either case,  $\Gamma(m)$  can be expressed as a definite integral. The distribution law expressed by equation (1) is known as the Student (1908) distribution law with  $n-1$  degrees of freedom. The range  $R$  of critical values of the function  $t$  is taken as the set of values of  $t$  outside the interval  $(-t_\delta, t_\delta)$  where  $t_\delta$  is given by the relation

$$\int_{-t_\delta}^{+t_\delta} dF(t) = 1 - \delta$$

This means that the probability is  $1 - \delta$  that the sample will be such that

$$-t_\delta < \frac{\sqrt{n}(\bar{x} - \mu_0)}{s} < +t_\delta \quad (2)$$

when the sample is actually from a normal population with mean  $\mu_0$ . If the sample yields values of  $\bar{x}$  and  $s$  so that the inequality (2) is not satisfied the hypothesis is rejected that the sample is from a normal population with mean  $\mu_0$ . The risk of rejecting this hypothesis falsely is measured as the type-I error  $\delta$ . Tabulations of values of  $t_\delta$  have been presented in various statistical books for  $\delta = .01, .05$ , and other values and for different values

of  $n - 1$ . There are many applications of the Student  $t$ -test.

**The Chi-Square Test.**—As a second example, consider an infinite population in which each element belongs to one and only one of the mutually exclusive classes  $A_1, A_2, \dots, A_k$  having probabilities  $p_1, p_2, \dots, p_k$ , where

$$\sum_{i=1}^k p_i = 1$$

In a sample of  $n$  elements from this population, the probability of getting  $x_1 A_1$ 's,  $x_2 A_2$ 's,  $\dots$ ,  $x_k A_k$ 's is given by the multinomial law

$$m(x_1, x_2, \dots, x_k) = \frac{n!}{x_1! x_2! \dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k}$$

It is important in many statistical problems to test whether the observed frequencies  $x_1, x_2, \dots, x_k$  could have reasonably come from a population in which  $p_1, p_2, \dots, p_k$  have specified values  $p'_1, p'_2, \dots, p'_k$ ; i.e., whether the  $x$  values depart significantly from their expected values  $np'_1, np'_2, \dots, np'_k$  under the hypothesis that the sample came from a population with these specified  $p$  values. The criterion for testing this hypothesis which was originally proposed by K. Pearson (1900) is:

$$\chi^2 = \sum_{i=1}^k \frac{(x_i - np'_i)^2}{np'_i} \quad (3)$$

known as the chi-square test criterion. It will be seen that it satisfies the intuitive requirement that it should somehow measure the discrepancy between each  $x_i$  and its expected value. The more the  $x$  values depart from their mean or expected values, the larger the value of  $\chi^2$  (chi-square). Thus, the range  $R$  of critical values which suggests itself consists of all values of  $\chi^2$  greater than a suitable chosen value  $\chi^2_\delta$ . For larger values of  $n$ , and assuming that none of the  $p$  values are very small, the sampling distribution of  $\chi^2$ , if the hypothesis is true that the sample came from a population in which the  $p$ 's have the values specified, is approximately

$$dF(\chi^2) = \frac{\left(\frac{\chi^2}{2}\right)^{\frac{k-3}{2}}}{2\Gamma\left(\frac{k-1}{2}\right)} e^{-\frac{1}{2}\chi^2} d(\chi^2) \quad (4)$$

This is an important sampling distribution, known as the chi-square distribution with  $k - 1$  degrees of freedom. Values of  $\chi^2_\delta$  have been tabulated for which

$$\int_{\chi^2_\delta}^{\infty} dF(\chi^2) = \delta$$

has various values from .01 to .99 and for values of  $k$  from 2 to 30. There are many statistical functions having sampling distributions that are of the form given as equation (4).

As a simple example of the application of equation (3), suppose a bridge player has kept a record of the number of aces he has obtained in each of 500 bridge hands. Suppose he received no aces in 165 hands, one ace in 210 hands, and more than one ace in 125 hands. Is this distribution of aces consistent with the hypothesis of thorough shuffling and fair dealing? Under the hypothesis of thorough shuffling and fair dealing one finds by applying the theory of combinations (see COMBINATORIAL ANALYSIS) that the probabilities of no aces, one ace, and more than one ace are approximately 0.30, 0.44, 0.26, respectively. The expected numbers of hands containing no ace, one ace, and no aces in 500 hands are, therefore, 150, 220, 130, respectively. The value of  $\chi^2$  computed from equation (3) is

$$\chi^2 = \frac{(165 - 150)^2}{150} + \frac{(210 - 220)^2}{220} + \frac{(125 - 130)^2}{130} = 2.147$$

This is not a significantly large value of  $\chi^2$ . For example, in a large number of sets of 500 bridge hands more than 30% of the sets would yield hands deviating more widely from the expected distribution of aces than in the present case. To have significant

discrepancies at the 0.05 probability level the observed distribution of aces would have to yield a value of  $\chi^2$  equal to about 6 or larger.

**Analysis of Variance.**—With the rapid development of statistical theory, an increasing amount of attention is being paid to the original design or setting up of any type of an experiment or an investigation which depends heavily upon statistical analysis of the results for interpretation. Consideration of experimental design led to the development of theory and procedures for determining what combinations of factors important to the entire experiment should be introduced to simplify statistical analysis of the data and its interpretation, and also to determine how many repetitions or replications of the experiment should be performed to detect important differences in experimental results attributable to the various factors or combinations of factors. R. A. Fisher was the leading exponent of the importance of carefully designed experiments. Fisher and his school developed experimental designs together with an appropriate statistical procedure known as analysis of variance for analyzing the data from such experiments. The principal idea in this work is to arrange the entire experiment in an orderly manner as a set of subexperiments (which may consist of as few as one trial each), these subexperiments differing from each other by varying one or more factors, so as to permit the effect of the variation of the factor (or factors) on the outcome of the experiment to assert itself in case there is such an effect. A statistical test function is designed to detect whether the outcome of the experiment is such that the differences in results from one subexperiment to another are attributable to the variation of the factors being tested, or whether they are simply chance differences; and to measure such differences if they are statistically significant (i.e., unlikely to have occurred by chance).

Suppose samples are drawn from each of two populations that have normal distribution laws with equal variances. The question is this: could the two samples have reasonably come from normal populations with the same mean? If the numbers of items, means, and variances of the two samples are  $n', n''; \bar{x}', \bar{x}''; s'^2, s''^2$ , respectively, a suitable criterion for making the test is  $\sqrt{n}(\bar{x}' - \bar{x}'')/s$  where  $n = n' + n''$ , and

$$s^2 = \frac{(n' - 1)s'^2 + (n'' - 1)s''^2}{n' + n'' - 2}$$

Thus, the greater the difference between the sample means in relation to  $s$ , the greater the value of the criterion and the more unfavourable it is to the hypothesis of equality of population means. This criterion computed from pairs of samples from normal populations having the same means has a distribution law given by equation (1) with  $n' + n'' - 2$  degrees of freedom; i.e., with  $n - 1$  replaced by  $n' + n'' - 2$ . Therefore, if the absolute value of the criterion exceeds  $t_\delta$ , the samples' means are said to be significantly different at the  $\delta$  probability level, which means that the samples are likely to have come from normal populations with the same means with a risk of probability  $\delta$  of making a type-I error. This test is useful in testing whether the effects of two treatments  $A$  and  $B$  on a given measurable characteristic are significantly different; e.g., whether two rations  $A$  and  $B$  are different in their effects in increasing the weight of pigs. The experiment might be set up with 30 pigs of a given age to receive ration  $A$  and 30 more pigs matched with those in the first group on age and weight to receive ration  $B$ . Thus, there are two subexperiments. After a given time each of the 30 pigs in each sample would be weighed, and these two sets of weights would be the two samples of  $x$  values to be used in the criterion.

Note that in using the two-sample criterion described above it has been assumed that the variances of the populations are equal. Actually, it may be wished to test this assumption, assuming only that the two population distributions are normal. A criterion (sometimes called an  $F$ -ratio; sometimes written  $\mathcal{F}$ -ratio) is available for making this test, namely

$$\mathcal{F} = s'^2/s''^2$$

which has the following distribution law when the hypothesis of equal population variances is true:

$$dF(\mathcal{J}) = \frac{\Gamma\left(\frac{n' + n'' - 2}{2}\right)}{\Gamma\left(\frac{n' - 1}{2}\right)\Gamma\left(\frac{n'' - 1}{2}\right)} \left(\frac{n' - 1}{n'' - 1}\right)^{\frac{n' - 1}{2}} \mathcal{J}^{\frac{n' - 3}{2}} \cdot \left(1 + \frac{n' - 1}{n'' - 1} \mathcal{J}\right) - \frac{n' + n'' - 2}{2} d\mathcal{J} \quad (5)$$

which is known as Snedecor's  $\mathcal{J}$  distribution and defined on the interval  $(0, \infty)$ . The  $\mathcal{J}$  criterion is intuitively reasonable since small or large values of it are unfavourable to the hypothesis of equal population variances. The critical range  $R$  of values of  $\mathcal{J}$ , for a given level of significance  $\delta$ , is found by cutting off the lower tail of the distribution at  $1/\mathcal{J}_\delta$  and the upper tail at  $\mathcal{J}_\delta$  so that the probability of  $\mathcal{J}$  falling between  $1/\mathcal{J}_\delta$  and  $\mathcal{J}_\delta$  is  $1 - \delta$ . Equation (5) is the basic probability law involved in making statistical tests in analysis of variance.

Next, consider a slightly more elaborate experiment. Suppose it is desired to test whether the quality of screws of a given type as measured by number of defectives per 1,000 varies significantly from machine to machine or from operator to operator. An experiment might be designed along the following lines: consider eight machines and eight operators; let each operator make 1,000 screws on each machine, and let  $x_{ij}$  be the number of defectives in the 1,000 screws produced by the  $i$ th operator on the  $j$ th machine. Assume that  $x_{ij}$  is made up of the sum of four parts:  $m$  which is the same for all combinations of operators and machines,  $r_i$  an effect attributable to the  $i$ th operator,  $c_j$  an effect attributable to the  $j$ th machine, and a random error  $e_{ij}$ , which is normally and independently distributed for all combinations of  $i$  and  $j$  with mean zero and variance  $\sigma^2$ . Then  $x_{ij} = m + r_i + c_j + e_{ij}$ . The  $r_i$  and  $c_j$  may be thought of as corrections to  $m$ , which may be positive or negative;  $r_i$  a correction to be made for the  $i$ th operator; and  $c_j$  a correction of the  $j$ th machine. They are such that

$$\sum_{i=1}^8 r_i = \sum_{j=1}^8 c_j = 0$$

The  $x_{ij}$  are sample values and what is wished is to set up a criterion for testing whether the operator corrections  $r_i$  are all zero (i.e., no average change from operator to operator), and similarly whether the machine corrections  $c_j$  are all zero. The likelihood ratio or least squares criterion for testing for no significant variation from operator to operator is

$$7 \frac{\sum_{i=1}^8 (\bar{x}_{i.} - \bar{x})^2}{\sum_{i,j=1}^8 (x_{ij} - \bar{x}_{i.} - \bar{x}_{.j} + \bar{x})^2}$$

where  $\bar{x}_{i.}$  is the average of  $x_{i1}, x_{i2}, \dots, x_{i8}$ , with a similar meaning for  $\bar{x}_{.j}$ ;  $\bar{x}$  is the average of all  $x$  values. The denominator of this expression is rather insensitive to variations due to operators or machines although the numerator tends to be sensitive to operator variations, and the ratio tends to have large values if there is significant variation from operator to operator. The criterion has as its sampling distribution the  $\mathcal{J}$  distribution of equation (5) with  $n' - 1 = 7$ , and  $n'' - 1 = 49$  if there is no significant operator to operator variation, which provides a method of obtaining a critical value of the ratio beyond which it would be declared that operator variation is significant. A similar analysis would be made for testing significance of machine to machine variation.

**STATISTICS, MATHEMATICAL.** In traditional usage mathematical statistics denotes a conglomeration of mathematical discussions connected with efforts to most efficiently collect and use numerical data subject to random variation (see STATISTICS). These efforts can be classified as behaviouristic and inductive.

### BEHAVIOURISTIC APPROACH

Behaviouristically, mathematical statistics is concerned with methods people use in guiding their actions to minimize the chances of committing errors. More exactly, it may be defined as dealing with statistical decision functions (see below). The definition originates from the human habit (so-called inductive behaviour) of adjusting to pertinent frequency relations. For example, since accumulations of clouds are frequently followed by rain, people who see clouds when embarking on a trip may think of taking an umbrella. Vaccinated persons contract smallpox much less frequently than others; thus smallpox vaccination is almost universal. In these examples the decisions (to take an umbrella or not, to be vaccinated or not) are based on the relative frequency of specific occurrences and the possible consequences of the different decisions.

Thus mass vaccination is desirable if the vaccine frequently prevents disease and if it causes dangerous reactions only infrequently. Obviously, people prefer to speak in terms of certainty instead of in terms of relative frequency. However, either the nature of the phenomena or ignorance of their causes compel an indeterministic approach based on how frequently this or that happens.

Questions of relative frequency are the concern of the theory of probability (see PROBABILITY, MATHEMATICAL). It deals with so-called chance mechanisms that combine the unpredictability of a single trial with the stability of relative frequencies in a long series of trials. The probability is an idealization of the long-run relative frequency of an outcome of a chance mechanism. When the probability that a given coin will fall heads is said to equal  $\frac{1}{2}$ , it means that this unusual coin tends to fall heads one-third of the time in a long series of tosses.

In the theory of probability the term random variable denotes a variable quantity determined by a chance mechanism. If  $X$  is a random variable and  $x$  any specified number, then the relevant chance mechanism determines the probability  $P[X \leq x]$  that  $X$  will assume a value not exceeding  $x$ . This same mechanism determines the probability  $P[X = x]$  that  $X$  will equal  $x$ . The probability  $P[X \leq x]$ , considered as a function of  $x$ , determines the properties of the random variable  $X$  and is called its distribution function, or simply its distribution.

Solution of typical probability problems consists in determining the distributions of some random variables from the given distributions of other random variables. A typical result of elementary probability theory is the distribution of the so-called binomial variable  $X$  (see BINOMIAL THEOREM), defined as the number of successes in  $n$  independent trials, where the probability of success has the same value  $p$ . Here  $n$  is a positive integer and  $p$  an arbitrary number between 0 and 1. The distribution function of  $X$  so defined may be obtained from

$$P[X = x] = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x} \quad (1)$$

for  $0 \leq x \leq n$ . In particular, this formula may serve to compute the probability that in  $n = 10$  independent tosses, with a coin falling heads with a long-run frequency  $p$  of  $\frac{1}{2}$ , heads will appear not more than once, twice, and so on.

This example deals with a chance mechanism, the throw of a coin, repeated independently  $n = 10$  times; that is, the outcome of any given throw is assumed to have no effect on the outcome of the others. If the order in which heads may occur is ignored, there are  $n + 1 = 11$  possible outcomes: the number  $X$  of heads thrown may be 0, 1, 2, ..., 10.

The unpredictably varying outcomes of scientific experiments are treated as manifestations of a chance mechanism and the quantitative characteristics of these outcomes are treated as random variables. Simplifying severely, the results of the use of a vari-

cine on a particular subject may be expected to vary according to his individual susceptibility to the disease, to aftereffects of vaccination, and according to the degree of his exposure to infection with the disease.

The decision for or against mass vaccination may be based on an experiment using a random selection out of a large parent population (universe) of  $n$  (experimental) individuals to be vaccinated and an equal number of (control) individuals to be left untreated. Then all  $2n$  individuals are exposed to infection and observed. The outcome may be described by the number  $X_1$  of "good" results among the vaccinated and the number  $X_2$  of such results among the controls. The two variables  $X_1$  and  $X_2$  have the same set of possible values:  $0, 1, 2, \dots, n$ . It is assumed that  $X_1$  and  $X_2$  are random variables with approximate distributions represented by equation (1), with  $p = p_v$  for the vaccinated group and  $p = p_0$  for the nonvaccinated. The symbol  $p_v$  represents the proportion of individuals in the parent population for whom the vaccine would give "good" results;  $p_0$  stands for the proportion of the parent population for whom such results would be observed without vaccination. The desirability of mass vaccination depends on the values of  $p_v$  and  $p_0$ . Unfortunately these values are unknown and the decision for or against mass vaccination must be taken on the values of the random variables  $X_1$  and  $X_2$  found empirically from the sample of subjects in the experiment.

In practice, the outcomes of trials with a vaccine are not classified as just "good" and "bad," and many different trials are performed. In many situations there is a set  $A$  of possible actions  $a_1, a_2, \dots$  from which one must be selected. Also, the desirability of this or that action depends on the distribution  $F$  of some observable random variables  $X = (X_1, X_2, \dots, X_n)$ . The distribution  $F$  is unknown, at least in all details, and the choice of action has to be based on the observed values  $x = (x_1, x_2, \dots, x_n)$  of the random variables  $X$ . Each possible combination  $x$  of values of  $X$  is described as a possible sample point and the set of all such combinations is the sample space.

In the vaccine example there are only two observable random variables  $X_1$  and  $X_2$ . The sample space  $W$  consists of  $(n+1)^2$  different points with coordinates  $(0,0), (0,1), (1,0), \dots, (n,n)$ . The datum of the general problem also includes a family or set  $\Omega$  of possible distributions of the observable random variables  $X$ , described as the set of admissible hypotheses or the set of possible states of the universe. To each distribution  $F$  of the set  $\Omega$  there corresponds a "preferred" action, and for each  $F$  in  $\Omega$  and each possible action  $a$  in  $A$  there is a more or less explicitly ascertainable degree of desirability. The datum of the problem may (but usually does not) give the so-called a priori probabilities of the various distributions  $F$  of the set  $\Omega$  (see PROBABILITY: Inverse Probability).

In the vaccine example, when the population from which subjects are selected is large, the family  $\Omega$  of possible distributions of the two observable variables  $X_1$  and  $X_2$  is determined approximately by all combinations of two equations of type (1). If  $p_0$  (the potential proportion of "good" results in the parent population without vaccination) is greater or equal to  $p_v$ , then the preferred action is  $a_1$  (abstain from mass vaccination). On the other hand if  $p_v$  is greater then the preferred action is  $a_2$  (embark on mass vaccination) with the desirability of  $a_2$  increasing with the difference  $p_v - p_0$ .

Any systematically defined rule for selecting actions can have the following form: if the observations yield  $X = x'$ , then take action  $a(x')$ ; if the observations yield  $X = x''$ , then take action  $a(x'')$ , and so on, for all possible sample points. In effect a rule for making decisions must establish the action to be taken as a function of the sample point to be observed. This function  $a(x)$  is called the statistical decision function. Since  $X$  is a random variable, so is the degree of desirability of the action taken using a given decision function. The datum of the problem allows calculation of the probability (at least the limits within which the probability is inferred to lie) that a given decision function will lead to the adoption of a very undesirable action. Thus mathematical statistics may be defined as the mathematical discipline dealing with properties of statistical decision functions. The gen-

eral problem of mathematical statistics is to determine (from the data of the given problem) the particular decision function that has specified desirable properties; e.g., the decision function (if it exists) that minimizes the probability of a wrong decision.

Probabilities are involved in probability theory and in mathematical statistics; if the unknown is a probability, the problem is one of probability theory; if the unknown is a decision function, the problem belongs to mathematical statistics. The viewpoint and terminology used here are generalizations due to Abraham Wald (1902-50) of two earlier theories described below. While many mathematical statisticians would agree with this characterization of their field, others would feel it too restrictive.

**Theory of Testing Statistical Hypotheses.**—The theory of testing statistical hypotheses, developed in the 1930s by Jerzy Neyman and Egon S. Pearson, is a chapter of mathematical statistics referring to the case where the set  $A$  of possible decisions contains only two elements: action  $a_1$  and action  $a_2$  considered as the negation of  $a_1$  (e.g.,  $a_1$  = arrange a mass vaccination campaign, and  $a_2$  = do not). The terminology refers to statistical hypotheses and their rejection. A statistical hypothesis means any assumption regarding the distribution of the observable random variables. The fact that only two possible actions are contemplated implies the existence of two contradictory hypotheses  $H_1$  and  $H_2$  such that if  $H_i$  happens to be true then the preferred action is  $a_i$  for  $i = 1, 2$ . This indicates symmetry between  $H_1$  and  $H_2$  that usually disappears when the consequences of selecting a wrong action are considered. There are two different situations in which a wrong action may be selected; i.e., there are two different kinds of error possible in testing a hypothesis:

$(H_1, a_2)$  = the true hypothesis is  $H_1$  and the action taken is  $a_2$  which is reject  $H_1$

$(H_2, a_1)$  = the true hypothesis is  $H_2$  and the action taken is  $a_1$  which is accept  $H_1$ .

Alternatively,  $a_2$  may be described as acceptance of  $H_2$ , and  $a_1$  as rejection of  $H_2$ . Usually error  $(H_1, a_2)$  is qualitatively different from error  $(H_2, a_1)$ . According to the individual's subjective evaluation one of the errors may be judged more important to avoid than the other. The one held more important to avoid is called the error of the first kind; the other is called the error of the second kind. One of the hypotheses  $H_1$  and  $H_2$  is selected to be the hypothesis tested or the null hypothesis  $H$  so that unjust rejection of  $H$  represents the error of the first kind. Thus if  $(H_1, a_2)$  is more important to avoid than  $(H_2, a_1)$  the hypothesis tested is  $H_1$ . For two contemplated actions the definition of any statistical decision function is now equivalent to selecting a subset  $w$  of the sample space  $W$ , called the critical region or region of rejection. Then a rule is made to reject the tested hypothesis  $H$  whenever the observations determine a sample point falling within  $w$ , and to abstain from this action in all other cases. Thus to define a test means to select a critical region.

The general character of the problems of testing hypotheses may be illustrated in the simplest case where the set  $\Omega$  of admissible hypotheses contains only two hypotheses ( $H$  and its negation  $\bar{H}$ ), each specifying the distribution of the observable variables in all details. It is assumed that there is a clear distinction in the importance of avoiding the two kinds of error.

Noting the importance of avoiding the error of the first kind, arbitrarily select a small number  $\alpha$  called (somewhat inappropriately) the level of significance, and seek the critical regions  $w(\alpha)$  such that their use will insure that the probability of committing an error of the first kind cannot exceed  $\alpha$ . Ordinarily there are many such regions  $w(\alpha)$ ; select for use the one  $w_0(\alpha)$  that insures the greatest probability of avoiding the error of the second kind. The region  $w_0(\alpha)$  that satisfies these two conditions is called the most powerful critical region for testing  $H$  against  $\bar{H}$  at the level of significance  $\alpha$ . Its use insures that the probability (i) of rejecting  $H$  when  $H$  is true is no more than the preassigned level  $\alpha$  and, subject to restriction (i), the probability (ii) of rejecting  $\bar{H}$  when  $H$  is false is greatest.

After a region  $w_0(\alpha)$  is found (on occasion there are many) it is appropriate to compute the probability  $\beta$  [ $w_0(\alpha)$ ] (termed power) that the test will reject  $H$  when this hypothesis is false.

When the selected level of significance  $\alpha$  is very low then the power of the test is very low too, and application of the test does not hold much promise in "detecting the falsehood of  $H$ ." It may then be decided to take a greater risk in controlling the error of the first kind (i.e., a larger  $\alpha$ ) to increase chances of rejecting the hypothesis tested when it is false.

In summary, the basic concepts of the Neyman-Pearson theory are those of critical region, two kinds of error, and power of a test.

**Theory of Estimation.**—The problem of statistical estimation has two different forms, known as point estimation and interval estimation (more generally, estimation by a set). Both are particular cases of the general problem of mathematical statistics and refer to situations in which the set of contemplated actions contains (roughly speaking) a large number of actions, comparable with the number of distributions of the observable random variables  $X$ . More specifically, to each distribution  $F$  of the set  $\Omega$  there corresponds one particular preferred action  $a(F)$  belonging to  $A$ . In these circumstances the decision to take a particular action  $a(F)$  in a sense is equivalent to the assertion that the function  $F$  represents the distribution of  $X$ . Such assertions based on observed values of random variables represent the process of statistical estimation.

In many cases the possible distributions of observable random variables  $X$  are identified by values of one or more parameters  $\theta_1, \theta_2, \dots, \theta_r$ . Thus the distributions of variables  $X_1$  and  $X_2$  in the vaccine example are identified by values of two parameters  $\theta_v$  and  $\theta_o$ . In such situations the problem of estimation is reduced to that of making assertions regarding the values of all or of some of the parameters involved. Consider one particular parameter  $\theta$  with possible numerical values contained in interval  $(a, b)$ .

It is called point estimation of the parameter  $\theta$  when the statistical decision function contemplated has the following form: if the observations yield the sample point  $X = x$ , then  $\theta$  has the value  $\hat{\theta}(x)$ . Here  $\hat{\theta}$  stands for a function defined for all possible sample points and has its values in the interval  $(a, b)$ . The function  $\hat{\theta}$  so used is called a point estimator of  $\theta$ .

It is called interval estimation of  $\theta$  when the decision function contemplated depends on functions  $\hat{\theta}_1$  and  $\hat{\theta}_2$ , both defined over the sample space  $W$ , both having their possible values in the interval  $(a, b)$ , and when for every possible sample point  $\hat{\theta}_1 < \hat{\theta}_2(x)$ . Then the statistical decision function is defined as follows: if the observations yield  $X = x$ , then assert that  $\theta_1(x) \leq \theta \leq \theta_2(x)$ . In other words instead of trying to predict the exact value of  $\theta$ , interval estimation involves an effort to predict the limits  $\hat{\theta}_1(x)$  and  $\hat{\theta}_2(x)$  within which this value presumably lies.

Suppose functions  $\hat{\theta}_1(x)$  and  $\hat{\theta}_2(x)$  are defined. Substituting random variable  $X$  for its particular value  $x$  produces a random interval  $I(X) = [\hat{\theta}_1(X), \hat{\theta}_2(X)]$ . This interval is called an interval estimator of  $\theta$ .

Explicit consideration of the problems of point estimation goes back at least to Galileo, but the major early figures in the development discussed here were Pierre Simon Laplace (1749–1827) and Carl Friedrich Gauss (1777–1855). Their view, adopted by A. A. Markov (1856–1922) and subsequently generalized by Wald, may be described by comparison with a game of chance in which the statistician can never win, but can lose an amount that increases with the size of the error of estimation. For every possible value  $\theta_1$  of the estimated parameter  $\theta$ , and for every possible value  $\theta_2$  of the point estimator, there is assumed a loss function  $L(\theta_1, \theta_2) \geq 0$  representing the amount to be paid by the statistician if  $\theta = \theta_1$  and he asserts that  $\theta = \theta_2$ . The exact nature of the loss function must be specified by practical considerations; Laplace considered  $L(\theta_1, \theta_2) = |\theta_1 - \theta_2|$ ; Gauss preferred  $L(\theta_1, \theta_2) = (\theta_1 - \theta_2)^2$  and subsequently other loss functions were considered. The various aspects of point estimation are based on different limitations imposed on the estimator, on different loss functions adopted, and on different definitions of optimum properties of an estimator. Here is an example:

(a) The estimator  $\hat{\theta}(X)$  shall be a linear function of the observable random variables  $\hat{\theta}(X) = a_1X_1 + a_2X_2 + \dots + a_nX_n$ .

This restriction ensures that the estimator will be easy to compute.

(b) The estimator  $\hat{\theta}(X)$  shall be unbiased; i.e., its mathematical expectation shall be equal to the parameter  $\theta$ .

(c) The loss function  $L(\theta_1, \theta_2)$  shall be equal to the square of the error of estimation (i.e., shall be Gaussian).

(d) Under conditions (a), (b), and (c), the estimator  $\hat{\theta}(X)$  shall minimize the mathematical expectation of the loss.

This particular problem was first formulated by Gauss who made a very elegant broadly applicable solution that became known as the method of least squares (see LEAST SQUARES, METHOD OF). Developments in this direction include the study of estimators subject to conditions (c) and (d), but not necessarily (a) and (b); loss functions other than the Gaussian also are considered.

Although vague ideas underlying interval estimation can be traced to the end of the 18th century, the first clear statement was formulated in 1931 by Harold Hotelling. In the 1930s a comprehensive theory was developed by Neyman. The basic concept here is that of the confidence interval. It is said that the interval estimator  $I(X)$  is a confidence interval for estimating  $\theta$  at the confidence coefficient  $\alpha$  if, whatever be the value  $\theta$  of the estimated parameter  $\theta$ , the probability that the interval  $I(X)$  will cover  $\theta$  is at least equal to  $\alpha$ .

It is shown that (in many cases) more than one confidence interval for a given parameter can be found, all corresponding to the same confidence coefficient  $\alpha$ . In such cases the problem of optimality arises, an important section of the theory. A typical problem is as follows:

(a) For a given confidence coefficient  $\alpha$  (say  $\alpha = .99$ ), and whatever be the true value  $\theta$  of the parameter  $\theta$ , the interval estimator  $I_\alpha(X)$  shall cover  $\theta$  with probability equal to  $\alpha$ .

(b) Whatever be the true value  $\theta_1$  of  $\theta$ , whatever be the false value  $\theta_2$  of the same parameter, and whatever be the interval estimator  $I(X)$  satisfying (a), the interval estimator  $I_\alpha(X)$  shall cover the false value  $\theta_2$  less frequently (more precisely, not more frequently) than  $I(X)$ .

If an estimator  $I_\alpha(X)$  satisfying (a) and (b) exists, it is called the shortest confidence interval for estimating  $\theta$ . The systematic use of shortest confidence intervals (to estimate the same parameter or different parameters) insures the prescribed long-run frequency (e.g., 99%) of correct assertions combined with the greatest precision of such assertions understood in the sense of condition (b).

**Theory of Experiments.**—Statistical considerations initiated an important scientific discipline called theory of experiments or design of experiments. The first attempt to build a unified theory was by Ronald A. Fisher (1930s) who sought ways of designing experiments to provide more relevant information than others requiring the same investment in funds and effort. Thus originated the systematic study of optimal designs.

Fisher and his school were chiefly concerned with designs of single experiments, with what might be called experimental tactics. Developments concerned with experimental strategy are due to Wald (1940s), and deal with a sequence of experiments that in principle may be continued indefinitely.

Fisher originally was concerned with agricultural experimentation. Later it was found that the same kinds of problems are encountered in almost all experimental work. One of these problems is that of biased selection of material used in experiments. To avoid such bias he introduced the principle of randomization (see RANDOMIZATION), an outstanding achievement.

Many experimental tactics introduced by Fisher and developed by his school are meant to diminish the effects of variability in experimental material, and include such specific designs as randomized blocks and Latin squares (see MAGIC SQUARE). In testing a drug on mice, the randomized blocks design consists in using  $N$  litters of mice and in selecting at random from each litter for example, three mice to be treated and another three to be left untreated. The six mice of each litter so selected constitute one randomized block. Considering substantial hereditary variation from one litter to the next, intuition and theory agree that such an experiment is less subject to random error than one based on unrestricted randomization of  $6N$  mice.

Fisher was also concerned with the possibility of experiments answering several questions at once. This may be illustrated by an elegant example due to Frank Yates. Consider an effort to weigh three objects A, B, and C with a balance that has an undetermined (changeable) zero point so that at each weighing the indicator has to be read while there is no load. Let the symbol (1) denote such a reading; also let (A), (B), ..., (BC), and (ABC) stand for readings when the scale is loaded with A alone, with B alone, ..., with B and C combined, and with A, B, and C combined.

An estimate of weight A will be provided by the difference  $(A) - (1)$ ; i.e., weight A differs from  $(A) - (1)$  only by an unavoidable random experimental error. One method of weighing A would be to make some (say  $4n$ ) independent readings (1) and the same number of (A), to compute  $4n$  differences  $(A) - (1)$  and to average them. Done separately for all three objects A, B, and C, the total number of readings would be  $24n$ . With the so-called factorial design due to Fisher, estimates of these three weights of exactly the same precision may be made from only  $8n$  readings. This is done by making  $n$  independent readings each of (1), (A), (B), (C), (AB), (AC), (BC), and (ABC). To estimate weight A arrange the  $4n$  differences as follows:

$$\begin{aligned}(A) - (1) \\ (AB) - (B) \\ (AC) - (C) \\ (ABC) - (BC)\end{aligned}$$

It may be seen that each of these differences is an independent estimate of weight A and that the average of  $4n$  of them is just as precise an estimate as the average of  $4n$  differences  $(A) - (1)$ . The same readings provide an estimate of weight B as follows:

$$\begin{aligned}(B) - (1) \\ (AB) - (A) \\ (BC) - (C) \\ (ABC) - (AC)\end{aligned}$$

A similar procedure is used for weight C. Thus one factorial experiment of  $8n$  readings can yield the precision requiring three times as many readings arranged conventionally.

A limitation on factorial designs is imposed by the requirement that the treatments studied must be additive. In the example just given (assuming a robust balance is used) this condition will be satisfied so that, apart from random error,  $(A) - (1)$  is equal to  $(AB) - (B)$ , and so on. However, if the phenomena studied are not weights but the effects of chemical elements in fertilizers (e.g., nitrogen, potassium, and phosphorus) on the yield of wheat per acre, then the effect of nitrogen alone  $(N) - (1)$  need not (and usually does not) equal the effect of the same nitrogen in the presence of potassium  $(NK) - (K)$ , and so on. Thus in such a case the use of fractional design may lead to unexpected complications.

In problems of experimental strategy concerned with sequences of tactically correct experiments, after  $n$  experiments have been completed there are different ways in which the  $(n+1)$ th experiment may be designed. There is also the possibility of discontinuing experimentation and reaching a so-called terminal decision. The problem of experimental strategy is to develop rules for using the results of  $n$  completed experiments to decide what to do next. The statement of the general problem and some remarkable mathematical developments were published by Wald (1950). One strategic problem of experimentation has attracted considerable attention and created a substantial literature. It is known as the problem of the Robbins-Monroe procedure and consists in the following.

For every number  $x$  in the interval  $(a, b)$  an experiment can be made yielding a value of a random variable  $Y(x)$ . Only a limited amount of information is available about  $Y(x)$ . However, this random variable is known to have an expectation  $M(x)$ . The exact nature of the function  $M(x)$  is not known except that it is continuous and increasing and that for some value  $x_0$  of  $x$  it is equal to zero. The experimental problem consists in determining the approximate value of  $x_0$ . The Robbins-Monroe procedure for attaining this goal begins by selecting in  $(a, b)$  an arbitrary number  $x_1$ , perhaps the midpoint of  $(a, b)$ , and in observing  $Y(x_1)$ .

Let the observed value be  $y_1$ . Then using the values  $x_1$  and  $y_1$  another choice is made of a number  $x_2$  within  $(a, b)$  and an experiment is made to observe  $Y(x_2)$ . The result of this observation is denoted by  $y_2$ . By continuing this procedure it is hoped to obtain a sequence of numbers  $x_1, x_2, \dots, x_n, \dots$  approaching the unknown  $x_0$  as a limit. The problem of experimental strategy is to determine how best to use the observed values of  $x$  and  $y$  to choose  $x_{n+1}$  so that the sequence of  $x$  values converges rapidly to  $x_0$ .

The characteristic feature that identifies this as a problem of experimental strategy is the chainlike dependence of the arrangements for the  $(n+1)$ th experiment on the designs and on the outcomes of the earlier experiments.

### INDUCTIVE APPROACH

A view that is sharply antagonistic to the behaviouristic approach is represented by several inductive schools of thought symbolized by the names of Fisher and Harold Jeffreys. As in the behaviouristic approach, all these schools are concerned with the best utilization of data subject to random variation. Hence their ultimate results (unavoidably) are particular statistical decision functions; that is, the conclusion is based on the observational data. However, the statistical decision functions are not considered explicitly; when a particular function is proposed, arguments in its favour are formulated not in terms of the consequences of its use but in terms of degrees of confidence in the underlying hypotheses. Essentially each inductive school begins by laying down one or more basic formulas (posterior probability of a hypothesis in some cases, likelihood and fiducial probability in others) represented as norms of human beliefs and actions. The handling of these formulas is then labeled by such terms as inductive reasoning or scientific inference. More radical inductive arguments in favour of a particular point estimator (called maximum likelihood estimator) ignore the consequences of its systematic use but refer to the fact that the estimator maximizes the likelihood described (Fisher) as "the mathematical quantity ... appropriate for measuring our order of preference. . . ." In relatively simple problems the decision functions developed by inductive schools frequently coincide with those of behaviouristic theory. In particular, as shown by Hotelling, Joseph L. Doob, and Wald, the maximum likelihood estimators have desirable properties in a broad category of problems. However, in the 1960s these inductive systems represented major areas of controversy in mathematical statistics.

### HISTORICAL BACKGROUND

Development of the conceptual content of mathematical statistics was gradual, extending over a century and a half. As noted earlier the behaviouristic approach to problems of estimation is found in the work of Laplace and Gauss. Laplace seems one of the first to test statistical hypotheses; but at that time there was no question of mathematical statistics as an independent discipline. Laplace's criteria for testing statistical hypotheses were intuitive rather than mathematical and in no way similar to his approach to the problem of point estimators. The behaviouristic approach to estimation was soon forgotten.

Mathematical statistics as an independent discipline seems to have appeared in the latter part of the 19th century in the work of A. Quételet, G. T. Fechner, K. Pearson (*qq.v.*), E. Czuber, G. U. Yule, and V. I. Bortkevich. The then existing branches of applied mathematics, (e.g., analytical mechanics) were, so to speak, individualistic. Many scientific problems required a new mathematical discipline concerned with aggregates of objects, all of which satisfy a specific definition but differ in individual characteristics. Such an aggregate (population) might be all men of military age in a country; these men differ in height. Another population would be the set of gas molecules in a container; each molecule has a unique velocity as its individual characteristic.

However, any population has its own characteristics, conditioned by those of the individual members, but essentially different. Gas pressure is a characteristic of the population of molecules con-

ditioned by their velocities; temperature is another such characteristic. These are examples of what Fechner called *Kollektivmass*. The average height of recruits is also a *Kollektivmass*, as is the frequency with which they are found with height between 5 ft. 10 in. and 5 ft. 11 in. The set of such frequencies (the frequency distribution) is also a *Kollektivmass*.

In the late 19th and early 20th centuries mathematical statistics emphasized the *Kollektivmasslehre*, a mathematical discipline concerned with collective characteristics of populations. The term descriptive statistics was introduced to mean the use of a variety of methods (including graphical and tabular methods) for describing such characteristics of populations. An important method of descriptive statistics is to consider a family of flexible curves or surfaces (depending on a moderate number of parameters) that can be used to approximate the empirical frequency distribution. A number of such families was developed, all representing interpolation formulas. The most successful system seems to be that due to Karl Pearson.

A conceptual problem studied by Wilhelm Lexis (1837-1914) developed to deprive *Kollektivmasslehre* of its independent status. Lexis was concerned with the year-to-year fluctuation of sex ratio among children born in a city, and similar ratios arising in the study of vital statistics. The question was whether an empirical index of dispersion is consistent with the assumption that determination of sex is governed by a simple chance mechanism such as a toss of a coin. This renewed a continuing effort concerned with chance mechanisms acting on individuals to produce the observed collective characteristics.

Interest in flexible formulas specifically developed to fit empirical distributions gradually decreased, except for those that could be deduced from clearly defined chance mechanisms. In the 1920s George Pólya constructed a system of chance mechanisms that can generate almost all the distributions of Karl Pearson's system. Thus mathematical statistics shifted from *Kollektivmasslehre* to the construction of chance mechanisms or (as they are called) stochastic models of phenomena. This idea was explicitly stated by Émile Borel (1871-1956): "The basic problem of mathematical statistics is to invent a system of simple chance mechanisms, such as throws of a coin, so that the probabilities determined by this system agree with the observed relative frequencies of the various details of the phenomena studied."

Although Borel's definition was appealing, developments following its formulation indicated that it leaves mathematical statistics without a field of its own. Depending on the attitudes of given research workers, stochastic models belong to the relevant substantive fields or to the theory of probability. Thus stochastic models of hereditary phenomena are an integral part of genetics; stochastic models of epidemics are an integral part of epidemiology; and so on. However, considerable literature on stochastic processes developing in time (e.g., birth and death stochastic processes constructed to represent the growth of biological populations) is one of the most active sections of the theory of probability. Each problem of the theory of stochastic processes is reducible to that of determining probabilities (e.g., that a biological population will eventually die out). While the field indicated in Borel's definition continued to grow in importance, it was claimed by other disciplines, leaving nothing to mathematical statistics.

While these ideas were in the process of dissolution, increasing effort was given to problems of estimation and of testing hypotheses. In connection with his system of curves, Karl Pearson developed a method of point estimation known as the method of moments; in 1900 he published his famous  $\chi^2$  (chi-square) test for goodness of fit. In 1908 F. Y. Edgeworth (1845-1926) found that consistent use of the method of moments must yield an excessive frequency of large errors of estimation (a distinctly behaviouristic approach) and proposed a new method of estimation, conjectured to be much better. Fourteen years later, Fisher discussed the same ground more rigorously and intensively. He introduced the term method of maximum likelihood. Student (pseudonym of W. S. Gosset) and Fisher developed a number of tests of particular hypotheses. However, studies of this kind were

not yet connected by any unifying idea, and were limited to particular decision functions. Problems of testing hypotheses and of estimation remained unrecognized as an independent field for systematic study.

Such recognition came when Fisher (1922) gave a new definition of statistics. Stating that the object of statistical methods is the reduction of bulky data, Fisher distinguished three basic problems: those of specification of the kind of population from which the data come (i.e., of the *Kollektivmass*), of estimation, and of distribution (probabilistic problems connected with point estimation). This was followed by a paper concerned specifically with the theory of estimation; the ideas underlying these papers are distinct precursors of the behaviouristic approach to mathematical statistics described earlier.

**STATIUS, PUBLIUS PAPINIUS** (c. A.D. 45-96), one of the principal epic and lyric poets of the silver age of Latin literature, was born in Naples. His father was also a poet, and Statius seems to have been trained as one from childhood. Little is known of his life. He lived in Rome, and was a court poet under the emperor Domitian, who awarded him a prize at the poetic festival at Alba, in A.D. 89 or 90. He was, however, unsuccessful in the Capitoline competition, probably on its third celebration in 94, and shortly afterward he returned to Naples.

The role of court poet seems to have suited Statius. His flattery is as different from the gentle propitiatory tone of Quintilian as it is from the exaggerated humility of Martial. Statius adopted without scruple the flattery that was inevitable under Domitian, exploiting it in a way which suited his own nature. He was exceptionally talented, and his poetic expression is, with all its faults, richer, as well as more buoyant and felicitous than is generally to be found in silver Latin.

Statius is at his best in his occasional verses, the *Silvae*, in five books containing 32 poems altogether, of which all but 6 are in hexameters. Five poems are devoted to flattery of the emperor and his favourites. Another group gives picturesque descriptions of the villas and gardens of the poet's friends. The *Kalendae Decembres* gives a striking description of the gifts and amusements provided by the emperor for the Roman populace at the Saturnalia. In his attempt at an epithalamium Statius is forced and unhappy, but his birthday ode in Lucan's honour has, along with the accustomed exaggeration, some good lines, and shows appreciation of earlier Latin poets. Those poems, too, which deal with family affection or personal loss are moving, and the short poem to Sleep (v, 4) is deservedly famous.

Statius also wrote two epics, the *Thebais* (in 12 books) and the *Achilleis* (in two, unfinished). The latter gives a charming and accomplished account of the early education of Achilles by Chiron the centaur, and of his being hidden in girl's clothing among the daughters of Lycomedes by his mother, Thetis, in order to save him from the Trojan war. He is discovered by Odysseus and taken off to Troy; but at this point the poem was evidently interrupted by the poet's death.

The *Thebais* is a more ambitious work, describing the struggle of the brothers Polynices and Eteocles for the throne of Thebes. It has been called an "episodic" epic; but apart from one long digression it keeps to its theme well enough. It has many features borrowed from Virgil, such as the catalogue of warriors, the games and the battle scenes. It often suffers from overstatement and exaggeration, and some of the scenes of horror are too gruesome.

but many more are admirable and original, such as the fight between Tydeus and his pursuers in book ii and the martyrdom of Menoeceus in book x. The work begins and ends with two passages, the fight in a storm between the two young warriors on the threshold of the king's palace at Argos and the meeting of Polynices' mother and sister at night on the battlefield, which convey an atmosphere of dramatic tension and reveal considerable tragic power.

Phillimore (*Silvae*, 2nd ed., 1918); in the "Loeb Series" with Eng. trans. by J. H. Mozley, 2 vol. (1928); *Silvae* with commentary by F. Vollmer (1898); *Thebais* i-vi with commentary by O. Müller (1870); *Achilleis* with English commentary by O. A. W. Dilke (1954). Eng. trans. of the *Silvae* by D. A. Slater (1908). (AN. K.)

**STATUTE OF LIBERTY:** *see* LIBERTY, STATUTE OF.

**STATUTE LAW.** A statute was defined by the famous English lawyer Sir Edward Coke (d. 1634) as "an Act of Parliament made by the King, the Lords and the Commons." The present article is restricted to this use of the term and, therefore, to statutes of the United Kingdom; for the U.S. and other countries, *see* LEGISLATION; LEGISLATURE; and the articles on the legal systems of individual countries.

Coke's definition is still apt in English law, except that in certain cases, provided for by the Parliament Act, 1911, a bill may become an act even though the House of Lords has not consented to it. The procedure for the enactment of statutes is regulated mainly by usage and the standing orders of Parliament. Church Assembly measures passed under the Church of England Assembly (Powers) Act of 1919 and presented for the royal assent after a favourable resolution of both houses of Parliament have the power and effect of acts of Parliament.

The earliest English statute is the Statute of Merton, 1235. Acts were engrossed upon the statute roll from the time (1278) of the Statute of Gloucester (6 Edw. I), but this practice has long been discontinued. Official copies of acts are now made on vellum and lodged at the Public Record Office and in the House of Lords. In the case of Church Assembly measures, a third vellum copy is printed and sent to the Church Assembly.

**Classification of Statutes.**—Acts of Parliament are classified as (1) public general acts; (2) local (or "local and personal") acts, including public acts of a local character; (3) private personal acts; (4) Church Assembly measures (*see* above).

Except for certain classes of private personal acts (such as naturalization and divorce acts), which are virtually obsolete, all acts of Parliament are printed by the queen's printer. There are two separate series of volumes, one containing the public general acts and Church Assembly measures, the other containing local and personal acts together with certain statutory orders.

For purposes of the law of evidence, however, a different classification applies, and by section 9 of the Interpretation Act, 1889, every act passed after 1850 is a public act unless the act expressly provides to the contrary. Such acts are judicially noticed and no proof of them is required. Acts stated not to be public acts are usually provable by the production of a queen's printer's copy.

Acts may also be classified according to their object by such terms as penal, beneficial, imperative, directory, enabling, disabling, taxing, codifying, consolidating, perpetual, temporary, and so forth. This last classification is important for the purposes of interpretation (*see* below).

Penal acts are those which impose a new disability; beneficial, those which confer a new favour. An imperative statute (often negative or prohibitory in its terms) makes a certain act or omission absolutely necessary and subjects a contravention of its provisions to a penalty. A directory statute (generally affirmative in its terms) recommends a certain act or omission, but imposes no penalty for contravention of its provisions. To determine whether an act is imperative or directory the act itself must be looked at, and many nice questions have arisen on the application of this rule of law to a particular case. Enabling statutes are those which enlarge the common law, while disabling statutes restrict it. Declaratory statutes, or those simply affirming the common law, once not

uncommon, are now practically unknown; the Treason Act, 1351 (25 Edw. III), is an example. Statutes are sometimes passed in order to overrule specific decisions of the courts. Examples are the Territorial Waters Jurisdiction Act, 1878, the Married Women's Property Act, 1893, and the Trade Disputes Act, 1906.

Every act has a short title by which it may be cited; *e.g.*, the Transport Act, 1962.

**Interpretation of Statutes.**—The Interpretation Act, 1889, provides an authentic interpretation for numerous words and phrases of frequent occurrence in statutes. Moreover, most modern acts contain an interpretation section which explains particular expressions in that act. The main body of the law on this subject is, however, to be found in judicial decisions; *i.e.*, the common law. The main rules are as follows: (1) The meaning of an act is primarily to be sought in the act itself. (2) The words of an act are to be construed in their ordinary and natural sense, unless there is something to the contrary in the context or in the scheme of the act. (3) The act is to be construed as a whole, and acts on similar subjects are to be construed together as forming one system. (4) Contemporaneous circumstances may be taken into account where the intention of the legislature cannot otherwise be ascertained. What is known as the rule in *Heydon's case* (1584) (3 Coke Rep., 7a) provides that the factors to be ascertained in this connection are: (a) the common law before the act; (b) the mischief or defect for which the common law did not provide; (c) the remedy Parliament has provided; and (d) the true reason for the remedy. (5) Where words can be interpreted in two different ways the inconvenient, unjust, or absurd consequences of adopting the one way may guide the court to adopt the other. (6) The full title and the preamble but not the short title, heading, or marginal note may be used for the purpose of interpreting the act as a whole, or in order to resolve any ambiguity. (7) Acts which purport to interfere with existing rights must be clearly expressed. (8) Statutes are to be interpreted, as far as their language admits, so as not to be inconsistent with the comity of nations or with the established rules of international law. (9) Some acts are to be liberally or benevolently construed, others strictly. Instances of those which fall into the former category are acts which are remedial; amending; explanatory; for the maintenance of religion, the advancement of learning, and the relief of the poor; directory as distinguished from mandatory or imperative enactments; and those in favour of the liberty of the subject. The acts to be strictly construed include those restricting the liberty of the subject; penal acts; fiscal and revenue acts; acts creating statutory powers and duties; private acts; acts affecting the prerogative of the crown, existing private rights, or the jurisdiction of the courts. In the case of penal statutes, for instance, strict construction means that the thing charged as an offense must be within the plain meaning of the words used; the words must not be strained as if there has been a slip or an omission, or as if the thing is so clearly within the intent of the legislature that it would have been included if thought of. Great care must be taken not to extend penal laws beyond what the legislature has clearly meant and adequately expressed. Similarly, in the case of taxation statutes the court is not to be guided so much by the objects which it thinks such acts are to achieve, as by considering whether the words of the act have reached the alleged subject of taxation. There is no presumption as to a tax; nothing is to be read in; nothing is to be implied. One can only look fairly at the language used. (10) Codifying and consolidating acts give rise to an inference of intention to reproduce the existing position and not to alter the law. A codifying act is, however, in the first instance, to be looked at without reference to the previous law if it is unambiguous, whereas reference is to be made to the previous law to ascertain the intention of the legislature in the case of an amending or consolidating act. (11) In construing acts, such as taxing acts, which apply to both England and Scotland, it is well settled that a construction should, if possible, be adopted which will make the incidence of taxation the same in both countries. (12) A special act which imposes mutual obligations on several parties so that it has a contractual operation should be construed in the same way as a contract to the same effect.

**Operation of Statutes.**—The date of the "passing" of an act is the date when it becomes law, *i.e.*, the date when it receives the royal assent; this date is also, in the absence of a provision to the contrary, the time of the "commencement" of the act, *i.e.*, the time when it comes into effect.

An act of the United Kingdom Parliament is to be construed *prima facie* as applying to the whole of the United Kingdom and not to any place outside. The United Kingdom does not include the Channel Islands or the Isle of Man.

An "extent" or "application" clause will, however, vary the effect of this rule. Acts are extended to apply to waters adjacent to the United Kingdom and other parts of the British Commonwealth (*see below*) for certain purposes.

An act generally applies only to those within the allegiance of the crown and does not extend to foreign subjects out of the queen's dominions. An act applicable to the queen's dominions is, if the context permits, to be construed as applying to all British subjects wherever they may be.

It is a clear rule of law that the crown is not bound by an act of Parliament unless it is expressly named or clear words of implication are used. The crown here includes the great departments of state, but bodies such as nationalized industries have been held not to be its servant or agent for this purpose. The crown may, however, be held to be bound by implication if the beneficent purpose of the act would be otherwise wholly frustrated; but it is entitled to the benefit of an act although not named.

Generally speaking the courts will hold that statutes are not retrospective, if it is possible so to construe them. This fundamental rule of English law involves another to the effect that a statute is not to be construed so as to have a greater retrospective operation than its language renders necessary. Where an act is repealed the repeal does not in general affect its previous operation.

The provisions of a public act can be overridden or varied only by express enactment or clear implication. Where the common law is to be changed, and especially the common law which a statutory provision has recognized and enforced, the intention of any new enactment to abrogate it must plainly exclude a construction by which both may stand together. Similarly, existing rights are not destroyed by a statute unless there are express words or the plainest implication to that effect. The principle applies whether the rights be common-law rights, rights of action, rights of ownership, or rights arising under a contract. Again, the jurisdiction of the superior courts over matters originally cognizable by them cannot be taken away except by express words or necessary implication. On the other hand, it has long been settled that the creation of a right of appeal is an act requiring legislative authority.

Temporary acts may be made perpetual or may be continued from time to time. The latter is now achieved largely by periodic Expiring Laws Continuance acts. The Army and Air Force acts are instances of temporary acts reenacted annually.

**Enforcement of Statutes.**—Crimes created by statute are tried either summarily or by indictment, and there are some which are tried by courts, such as courts-martial, having jurisdiction over a limited class of persons. Again, a breach of a statutory command in a matter of public concern is indictable at common law, and in the absence of a special statutory remedy the performance of a public duty may be enforced by indictment or by information filed by the attorney general. An injunction against a continuance of the breach may be granted in appropriate cases. An order of mandamus (a judicial writ in the sovereign's name) lies for the enforcement of a public duty provided there is no more appropriate remedy.

In some cases a person injured by a breach of statutory duty may bring proceedings to recover his loss. This holds only where no remedy for the breach by way of penalty or otherwise is prescribed, or where it appears that the duty is imposed for the benefit of particular persons.

The operation of an act may be suspended by a subsequent statute. Many instances of this occurred during World War II by means of emergency legislation. Similarly, an act may be repealed or amended by a later act. Repeal by implication may occur where the provisions of a later enactment conflict with the earlier,

but such repeal is never to be favoured. An act in its application to England cannot be repealed solely by disuse (*see below* as to Scotland). There is a presumption that, where statutory provision has been made for a specific class of cases, a subsequent general enactment is not intended to interfere with such provision. The Interpretation Act, 1889, contains many provisions relating to repeal.

**Delegated Legislation.**—Modern statutes tend increasingly to provide that a particular authority shall have power to make orders, rules, and regulations in relation to particular matters arising under the act. Power may also be conferred to make statutory orders in council. These were previously termed statutory rules and orders, but by the provisions of the Statutory Instruments Act, 1946, they were named statutory instruments, the procedure in relation to them being governed by that act. Copies of such instruments printed under the authority of Her Majesty's Stationery Office are receivable in evidence. Some hold that legislation by statutory instrument has gone too far and that Parliament itself should consider substantive legislation even if this requires the establishment of Scots and Welsh and possibly other regional legislatures in order to lighten the burden of the United Kingdom Parliament. (*See also ORDER IN COUNCIL.*)

**Scotland.**—Much of what has already been said applies to Scotland, although Scotland has its own provisions of law and its own courts whose decisions are often quite different from those of the English courts. A public general statute applies generally to Great Britain and Northern Ireland, which includes Scotland, unless otherwise stated. By the Private Legislation Procedure (Scotland) Act, 1936, which applies to Scotland only, where any public authority or persons desire a private act they may apply to the secretary of state for Scotland for a provisional order. In the absence of any opposition the secretary of state for Scotland is directed to introduce into Parliament a confirmation bill, and any resulting act is a public act of Parliament.

In the 17th and 18th centuries the Court of Session promulgated acts of sederunt (*i.e.*, of a judicial body) amounting to general legislation. In modern times these acts relate exclusively to procedure and are usually passed in virtue of a specific authority in some particular statute. In 1948 an act of sederunt approved new consolidated rules and repealed the provisions of any previous act inconsistent with them. An act of adjournment is an act passed by the High Court of Justiciary for regulating procedure in that court and in inferior criminal courts.

A statute may be impliedly repealed by falling into disuse. This rule is applicable only to Scots acts; *i.e.*, those passed before 1707. There is no analogous principle in England, and even in Scotland no statute passed after the union in 1707 has been held by the Scottish courts to have fallen into desuetude.

Scots acts, which are usually expressed briefly and without detailed provisions, have been interpreted in a very liberal spirit. In their construction it is a recognized rule that, whatever the literal meaning of the statutory words, they are to be read as interpreted by decisions pronounced shortly after the act was passed. Apart from this important difference, the rules of interpretation in Scotland are similar to those discussed above.

**Northern Ireland.**—The Parliament of Northern Ireland consists of the queen, the Senate of Northern Ireland, and the House of Commons in Northern Ireland. The Government of Ireland Act, 1920, deals with legislation in Northern Ireland and gives power to make laws for the peace, order, and good government of Northern Ireland with certain matters reserved to the United Kingdom Parliament. Parliament at Westminster does not in practice legislate for Northern Ireland in matters within the jurisdiction of the Northern Ireland Parliament although it has power to.

**British Commonwealth.**—Acts of the United Kingdom Parliament do not extend to self-governing Commonwealth countries, colonies, or dependencies unless these are specially named therein. Moreover, the United Kingdom Parliament cannot legislate for the self-governing countries without their consent. Colonies are either self-governing or crown colonies. By the Colonial Laws Validity Act, 1865, the "charter of colonial independence," any colonial law repugnant to the provisions of any act of Parliament

extending to the colony is void to the extent of such repugnancy, and no colonial law is to be void by repugnancy to the law of England unless it is repugnant to such an act of Parliament. For colonies without representative legislatures the crown usually legislates. The relationship between the U.K. Parliament and the self-governing countries' legislatures is dealt with by the Statute of Westminster, 1931.

**Other Countries.**—In most other countries, with the exception of the United States, there is a code of law. The assent of two chambers and of the head of the state is generally necessary to legislation.

The term "statute" is used by international jurists to denote the whole body of the municipal law of the state. In this sense, statutes are either real, personal, or mixed. A real statute is that part of the law which deals directly with property, whether movable or immovable. A personal statute has for its object a person and deals with questions of status such as marriage, legitimacy, and infancy. A mixed statute affects both property and persons and it is said to deal with acts and obligations. Personal statutes are of universal validity; real statutes have no extraterritorial authority. See also PARLIAMENT. (P. E. L.)

**STAUDINGER, HERMANN** (1881–1965), German chemist, awarded the 1953 Nobel Prize for chemistry for his work on the macromolecule. He was born on March 23, 1881, in Worms. He was educated in the universities of Halle, Munich, and Darmstadt. At Halle he became doctor of philosophy in 1903. He taught in Strasbourg, in Karlsruhe as professor of organic chemistry at the Technische Hochschule, and in Zürich as professor of general chemistry (1912–26). In 1926 he was elected to the chair of chemistry in Freiburg im Breisgau, where in 1940 he became director of the chemical laboratory and research institute for macromolecular chemistry. His main contributions to chemistry have been in the field of plastics. He showed that small molecules polymerize by chemical interaction, not simply by physical aggregation, and that linear molecules could be built up synthetically in this way by a variety of processes and maintain their individuality even when subject to chemical modification.

He further showed how it is possible to build up high-polymer networks and that these expanded only to a finite extent when immersed in suitable solvents. He established the relationship between the molecular weight of a high polymer and its viscosity in solution. After leaving the research institute for macromolecular chemistry in 1956, Staudinger wrote his memoirs, *Arbeitserinnerungen* (1961). Staudinger died in Freiburg on Sept. 8, 1965.

See further PLASTICS; POLYMERIZATION.

See E. Farber, *Nobel Prize Winners in Chemistry, 1901–1961* (1963). (D. McK.)

**STAUNING, THORVALD** (1873–1942), Denmark's leading Social Democratic statesman for a quarter of a century, was born in Copenhagen on Oct. 26, 1873, the son of an artisan. A tobacco-worker and an active trade unionist, he was elected secretary of the Social Democratic League in 1898 and a member of the *folketing* in 1906, becoming chairman of his party in 1910. His organizing ability and his realism served the Social Democrats well; and in 1916 he became minister in Carl Theodor Zahle's Radical government (1913–20), subsequently carrying through a number of social reforms. He opposed antiparlamentarian tendencies within the labour movement; and despite the "Easter crisis" of 1920 (see DENMARK: History), he established good relations with the Royal House. The elections of April 1924 enabled him to form the first Social Democratic government, which was supported by the Radical Liberals till disagreement over legislation to restore the economy brought about its fall in December 1926. When the elections of April 1929 gave the Social Democrats a huge majority, Stauning formed a coalition government with the Radical Liberals. Social reforms were prepared, and during the depression the government carried through extensive legislation by concluding "crisis agreements" with the opposition. Respected for his firm and always loyal conduct, Stauning transformed his party from an essentially working-class one into one that stood for a broad social policy; and in September 1936 his government's supporters won a majority in the *landsting* also. In 1939, how-

ever, Stauning's attempt to achieve a constitutional reform failed; and his later efforts to strengthen defense could not prevent the German occupation of Denmark in 1940. He died on May 3, 1942.

(F. Sk.)

**STAUNTON**, a city of Virginia, U.S., 110 mi. (177 km.) NW of Richmond, near the southern end of the Shenandoah Valley, is the seat of Augusta County. This city of narrow streets and steep hills was founded by John Lewis on land granted to William Beverley by King George II in 1736 and was named for Lady Rebecca Staunton, wife of Sir William Gooch, a colonial governor. Settled by Scotch-Irish and English, the town in 1738 became the seat of the newly organized county, which then stretched to the Mississippi River. It was an important junction point for travelers. During the American Revolution the Virginia General Assembly met for a brief period in Trinity Church there. The American Civil War twice brought Federal occupation.

Staunton is the heart of a general farming area that produces sheep, cattle, and apples. The manufacture of flour, furniture, clothing, air-conditioning units, and razor blades brought in new workers from the North and East. Mary Baldwin College, a Presbyterian school for women, was established in 1842. Stuart Hall, an Episcopal preparatory school for girls, was founded in 1843, and Staunton Military Academy, a private school for boys, in 1860. The Virginia School for the Deaf and Blind and two state hospitals are in the city. Woodrow Wilson was born in the manse of the First Presbyterian Church, and in 1941 the building was made a national shrine.

Incorporated as a city in 1871, Staunton in 1908 became the first city in the U.S. to adopt the city-manager form of government. For comparative population figures, see table in VIRGINIA: Population. (G. M. Be.)

**STAUROLITE**, a mineral consisting of basic aluminum and ferrous iron silicate. Crystals are orthorhombic and have the form of six-sided prisms. Interpenetrating cruciform twinned crystals are very common and characteristic; they were early known as *pierres de croix* or *lapis crucifer*, and the name staurolite, from the Greek words for "stone" and "cross," has the same meaning. In fig. 1 the twin plane is [032] and the two prisms intercross at an angle of  $91^{\circ}22'$ ; in fig. 2 the twin plane is [232] and the prisms

FIG. 1 AND 2.—TWIN CRYSTALS OF STAUROLITE

intercross at nearly  $60^{\circ}$ . The mineral is translucent to opaque and dark reddish-brown in colour. Waterworn pebbles of material sufficiently transparent for cutting as gem stones are occasionally found in the diamantiferous sands of Brazil. The formula is  $\text{FeAl}_4(\text{SiO}_4)_2(\text{OH})\text{O}$ . The hardness is 7.5; specific gravity 3.75. Staurolite is a characteristic mineral of crystalline schists, and it is also a product of contact metamorphism. It is found at various points in Virginia, North Carolina, and Georgia embedded in schist or weathered loose in the soil, often as fine twinned crystals that are prized as good luck charms (fairy stones). Lustrous brown crystals occur with kyanite on Monte Campione, Ticino, Switz., and large twinned crystals are found in the mica schists of Brittany. (Cl. F.)

**STAVANGER**, a major seaport of southwest Norway and the administrative centre of Rogaland fylke (county), lies at the mouth of Gandafjorden (Gannsfjord), an arm of Boknafjorden (Boknafjord), at the north of the rich agricultural and industrial district of Jæren, 200 mi. (322 km.) WSW of Oslo. Pop. (1965 est.) 78,435. Very little is known about its history before it be-

came a bishopric (c. 1125), which was later removed to Kristiansand in 1682. A Lutheran bishopric was created in 1925. Parts of the town centre still have a medieval appearance with narrow streets and wooden houses, but much has been rebuilt. The cathedral of St. Swithun, founded by the first bishop, Reinald, of Winchester, Eng., has been called the most interesting stone church in Norway after Trondheim Cathedral. Other places of interest include the Kongsgård Grammar School (1824), on the site of the former episcopal palace; the Valberg Tower; several parks; an art gallery; and two museums, one of which, the town museum in the Ledaal mansion (family home of the 19th-century novelist Alexander Kielland), also serves as the king's residence when he visits the town. Stavanger is the chief centre of the Norwegian canning industry and is the location of the Norwegian Canning School and the industry's central research laboratory. Shipbuilding is the other main industry. The chief exports are brisling, kippers, and other canned products. The town has an international airport at Sola, 9 mi. (14 km.) SW, and a fine harbour with a busy coastal and foreign traffic. It is also the terminus of the railway and road from Oslo and Kristiansand. (A. B. A.)

**STAVROPOL**, a town and administrative centre of the *kray* of the same name of the Russian Soviet Federated Socialist Republic, U.S.S.R., lies on the Stavropol Upland of the Caucasian foreland, near the source of the Grachëvka River. Pop. (1959) 141,023. The town was founded by General Suvorov as a fortress in 1777. Its position on the main highway from Russia to the Caucasus led to its development as an important military, administrative, and trading centre. This significance declined after the construction of the Rostov-Baku railway, which passes south of Stavropol. A branch railway now joins the town to the trunk line at Kropotkin. The town has a range of industries processing the produce of the rich farmland of its region: flour milling, wine and fruit juice making, meat-packing, butter making, leatherworking, to name the most important ones. Machine building and the clothing industry are also important. Stavropol is an attractive town, with tree-lined streets laid out on a gridiron pattern. It has medical, agricultural, foreign language, and pedagogic institutes, and a research institute for sheep and goat rearing.

The town in Kuybyshevskaya (Kuibyshev) Oblast', formerly called Stavropol, was renamed Togliatti in August 1964.

(R. A. F.)

**STAVROPOL KRAY** of the Russian Soviet Federated Socialist Republic, U.S.S.R., was formed in 1924. Area 31,120 sq.mi. (80,600 sq.km.): Pop. (1959) 1,882,911. The southern part of the *kray* forms the Karachayevo-Cherkesskaya (Karachai-Cherkess) Autonomous Oblast' (q.v.). The *kray* lies on the northern flank of the Greater Caucasus Range, and in the southwest its boundary lies along the crest line, with peaks such as Mt. Dombay-Ul'gen, 13,278 ft. (4,047 m.). This Caucasus region of the *kray*, with a series of parallel ranges, broken by deep, picturesque river gorges, lies within the Autonomous Oblast'. The greater part of the *kray* is occupied by the Caucasian foreland, known as the Stavropol Upland. This reaches 2,730 ft. (832 m.) in Mt. Strizhament. The upland falls away in the east to the Caspian Lowland and in the north to the Kumo-Manych Depression, through which the Caspian was formerly linked to the Sea of Azov. The larger part of the *kray* is drained to the Caspian by the Kuma and its tributaries, the west draining by way of the Kuban to the Sea of Azov. Many of the rivers are seasonal, and lakes are often saline. The great variety of relief gives rise to considerable climatic variation, but in general the climate is continental. Divnoye in the Manych Valley has a January average temperature of  $-6.1^{\circ}$  C ( $21^{\circ}$  F) and a July average of  $24.4^{\circ}$  ( $76^{\circ}$ ). Rainfall, except in the mountains, is low, from 18 in. (457 mm.) a year in the west to 12 in. (305 mm.) or less in the east. The mountains are characterized by vertical zones of vegetation: deciduous forest, coniferous forest, alpine meadow, and rock and ice. The upland and lowlands are mostly steppe on chernozem soils, but the natural grass vegetation survives in very limited areas. In the drier east, the Nogay Steppe, conditions become increasingly semidesert, with chestnut and saline soils and sage vegetation.

Of the 1959 population, about 31% (587,369) was urban, liv-

ing in 12 towns and 10 urban districts. The largest towns are the administrative centre of Stavropol (q.v.) (141,023) and the resorts of Kislovodsk (79,097) and Pyatigorsk (69,617). These last two places are the largest of a group of resort towns, deriving their importance from the abundant mineral springs of the Caucasus. Large deposits of natural gas, first discovered in 1910, are piped as far as Moscow. There are also several small oil deposits. Most industry in the *kray* is concerned with processing the produce of the highly developed agriculture, which dominates the economy. The chernozem soil area is up to 80% arable. Winter wheat and maize (corn) occupy the largest area, but industrial crops are very important, notably sunflowers, flax, mustard, castor beans, and potatoes. Fodder crops are widely grown in connection with the large-scale cattle and sheep rearing. Much of this is based on transhumance between the high mountain pastures in the summer and the dry Nogay Steppe in the winter.

(R. A. F.)

**STEAM**, the term commonly applied to vaporized water. In the pure state steam is an odourless, invisible gas, but when interspersed with minute droplets of water, it has a white cloudy appearance.

The generation of steam from water is one of the most important processes of our modern industrial age. Steam is used for heating many large office buildings, hotels, apartment houses, and factories. It is also widely used in industry for the manufacture of steel, aluminum, copper, nickel, and other metals; for the refining of oil; and for the production of chemicals and many other products. In the home, such items as steam irons are common appliances, and steam has long been used for cooking. In addition, it drives the huge turbogenerators that furnish the major portion of our electric power.

## I. PROPERTIES

To understand the properties of steam imagine a vertical cylinder containing one pound of water as illustrated in fig. 1A. Resting on the water is a weighted movable piston exerting a constant pressure on the contents. Imagine the water to be initially at room temperature—in this condition it is called subcooled liquid because it exists at a temperature below its boiling point. It occupies the volume indicated at point A' in fig. 1. Next imagine heat to be slowly added to the water until it reaches the boiling-point temperature and volume represented by point B', which is slightly greater than A'. In this condition the water is said to be in the saturated liquid state. The volume is often designated by the symbol  $v_f$ , meaning specific volume of the saturated fluid (liquid). If still more heat is added, boiling occurs and steam is formed underneath the piston, forcing it upward as illustrated in fig. 1C.

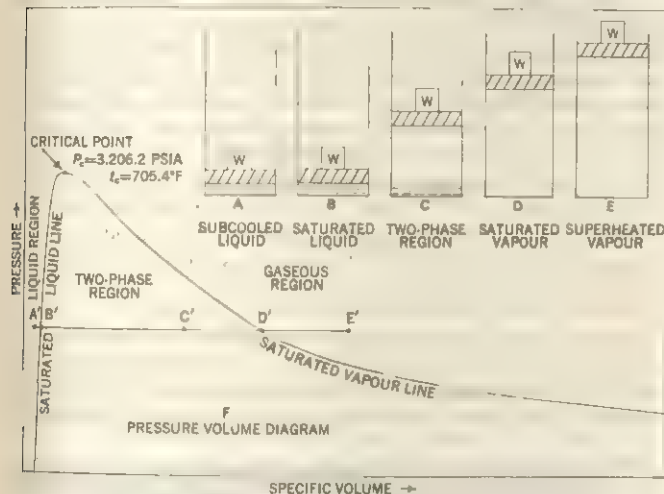

FIG. 1.—DIAGRAM ILLUSTRATING THE BEHAVIOUR OF STEAM. IN THE TWO-PHASE REGION (C) BOTH SATURATED LIQUID AND SATURATED VAPOUR ARE PRESENT

When liquid and steam coexist the contents are said to be in the two-phase region, meaning that the water exists in two physical forms, liquid and gas. As long as this condition exists, the mixture will remain at its boiling-point temperature because additional heat will merely cause more water to boil. Similarly, if heat is withdrawn, some of the steam will condense but the temperature will not change. Between points B' and D' in fig. 1F, therefore, the temperature is constant and will depend only on the pressure exerted by the piston. (See PHASE EQUILIBRIA.)

If just enough heat is added to vaporize the last droplet of liquid the entire volume will be occupied by steam. Under this condition the steam is said to be dry saturated and will be represented by the point D'. Its volume is usually designated by the symbol  $v_g$ , meaning specific volume of the saturated gas (vapour). If still more heat is added there will no longer be any liquid to boil, and the temperature will rise. In this condition the steam is said to be superheated, meaning that it is heated above its boiling- or condensation-point temperature. As indicated in fig. 1E, the volume of a pound of superheated steam is greater than the volume of a pound of saturated steam when both are under the same pressure. A typical point in the superheated region is that represented by E' in fig. 1F.

The temperature at which water will boil depends on its pressure. For example, at standard atmospheric pressure of 14.7 psia (pounds per square inch absolute), the boiling-point temperature of water is  $212^\circ\text{F}$  ( $100^\circ\text{C}$ ). If the pressure is reduced, the boiling-point temperature is also reduced. As the pressure is increased, more molecular activity is required to effect the escape of water molecules from the liquid into the gaseous state. This greater molecular activity requires a higher temperature. If the pressure is made just high enough to make escape impossible, the water is said to be at its critical pressure. The temperature of saturated liquid at this pressure is called the critical temperature

and is equal to  $705.4^\circ\text{F}$  ( $374.11^\circ\text{C}$ ). Since no boiling can occur under these conditions, saturated liquid and saturated vapour become identical. The point corresponding to this situation, called the critical point, is indicated in fig. 1F.

The amount of heat required to vaporize one pound of saturated liquid into one pound of saturated vapour is called the latent heat of vaporization. This latent heat varies with the pressure, being greatest at low pressures and diminishing to zero at the critical pressure.

The importance of steam for the heating of buildings, generation of power, and many other applications has resulted in a need to know its physical properties over a wide range of pressure and temperature. The most important properties of steam, described below, are its specific volume, internal energy, enthalpy, and entropy.

**1. Specific Volume.**—The specific volume is defined as the volume per unit mass. In the English system of units it is measured in cubic feet per pound. The variation of specific volume with pressure and temperature is illustrated by the pressure-volume diagram of fig. 2. The diagram presents the variation of volume with pressure along constant temperature lines, or isotherms. The diagram is divided into three regions: liquid, two-phase, and gaseous. Everything to the left of the saturated liquid line and below the critical temperature of  $705.4^\circ\text{F}$  is normally considered to be in the liquid region. Everything to the right of the saturated vapour line or above  $705.4^\circ\text{F}$  is normally considered to be in the gaseous region. At pressures above the critical this designation is quite arbitrary, since there is really no physical distinction between liquid and vapour across the critical temperature line. The two-phase region lies between the saturated liquid and saturated vapour lines. In this region lines of constant temperature are horizontal and therefore correspond to lines of constant pressure.

FIG. 2.—PRESSURE-VOLUME RELATIONS OF STEAM

Examination of one of the constant-temperature lines reveals that there is little change of volume with pressure in the liquid region, indicating that liquid water is almost incompressible. During boiling the specific volume increases at constant pressure and temperature until the saturated vapour line is reached, after which a reduction in pressure is required for an increase in volume at constant temperature.

Specific volumes along the saturated liquid line are designated as  $v_f$ , while those along the saturated vapour line are designated as  $v_g$ . In the two-phase region, which is sometimes called the saturated region, the fraction by weight of the mixture which is vapour is called the quality. It is usually designated by the symbol  $x$ . Thus, if at a given pressure 90% of the water-vapour mixture is saturated vapour and 10% saturated liquid, the steam would be said to have a quality of  $x = 0.90$  or 90%. From a knowledge of the quality the specific volume of the steam can readily be computed by adding together the fraction that is liquid times its saturated liquid specific volume and the fraction that is vapour times the specific volume of saturated vapour. Since the fraction that

is vapour is  $x$  and that which is liquid is  $(1 - x)$ , the specific volume in the two-phase region will be

$$v = (1-x)v_f + xv_g = v_f + x(v_g - v_f) = v_f + xv_{fg} \quad (1)$$

where  $v_{fg}$  represents the change in volume from liquid to vapour ( $v_g - v_f$ ).

**2. Internal Energy.**—The internal energy of steam is that energy possessed by virtue of the motion and configuration of its molecules. It is usually measured above a fixed datum state in which its value is arbitrarily taken as  $-0.185 p_f v_f$ , where  $p_f$  and  $v_f$  are the pressure and specific volume of saturated liquid at the freezing-point temperature of  $32^\circ \text{ F}$  ( $0^\circ \text{ C}$ ). The reason for this value will become clear in the following section on enthalpy. The internal energy is most frequently designated by the symbol  $u$  and in the English system of units is measured in British thermal units (BTU) per pound. As in the case of volume, it also varies with pressure and temperature and is designated at important states with the same subscripts. Thus

$u_f$  = internal energy of saturated liquid  
 $u_g$  = internal energy of saturated vapour  
 $u = (1-x)u_f + xu_g = u_f + xu_{fg}$   
 = internal energy in the two-phase region

**3. Enthalpy.**—The enthalpy of steam is a property obtained by adding the pressure-volume product to the internal energy. Thus, in consistent units,

$$h = u + \frac{144pv}{778} = u + 0.185pv \text{ BTU per pound} \quad (2)$$

In this expression  $p$  is the pressure in pounds per square inch absolute, and  $v$  is the specific volume in cubic feet per pound. The numerical constants 144 and 778 are conversion factors representing the number of pounds per square inch in one pound per square foot and the number of foot pounds in a British thermal unit, respectively. Thus, the units of enthalpy are the same as those of internal energy, British thermal units per pound.

In the Keenan and Keyes steam tables the value of enthalpy is arbitrarily taken as zero at 32° F and at 0.08854 psia, the saturation pressure corresponding to this temperature. It is for this reason that the internal energy  $u$  at this state is  $-0.185 p_1 v_1$ , as indicated in the previous section. The enthalpy varies with pressure and temperature in much the same manner as internal energy and at important states is designated with the same subscripts. Thus

$h_f$  = enthalpy of saturated liquid  
 $h_g$  = enthalpy of saturated vapour  
 $h = (1 - x) h_f + x h_g = h_f + x h_{fg}$   
 = enthalpy in the two-phase region

The importance of the enthalpy of steam arises from the fact that it occurs in the steady-flow energy equation. If changes in velocity and elevation during a flow process are neglected, the steady-flow energy equation between any two sections becomes

$$h_1 \neq {}_1Q_2 \neq {}_1W_2 = h_2 \quad (3)$$

where  $h_1$  and  $h_2$  are the enthalpies of the steam at sections 1 and 2, respectively, and  $\pm_1 Q_2$  is the heat added or abstracted and  $\pm_1 W_2$  the work done on or by the steam between the two sections, all in British thermal units per pound of steam. If heat is added in some device such as a boiler, where no work is done, the equation becomes

$$O_2 = h_2 - h_1. \quad (4)$$

This means that the difference in enthalpy is a measure of the heat added and that to compute the amount of heat added one need only subtract the initial enthalpy from the final enthalpy. Similarly, if one considers the flow of steam through a steam turbine, where  ${}_1Q_2 = 0$  and  ${}_1W_2$  is positive, the equation becomes

$$W_2 = h_1 - h_2 \quad (5)$$

The work done by the turbine is therefore obtained by subtracting the final enthalpy from initial enthalpy. Also, when water is vaporized into steam at constant pressure the amount of heat required (latent heat of vaporization) is equal to the difference be-

tween the final and initial enthalpies  $h_g - h_f$ , designated as  $h_{fg}$ .

4. **Entropy.**—The entropy of steam is a property defined mathematically by the equation

$$S = S_0 + \int \left( \frac{\delta Q}{T} \right)_{\text{rev}} \quad (6)$$

It is one of the most useful properties of steam and is employed for evaluating that portion of heat energy that is unavailable for conversion into useful work. A complete discussion of this property cannot be undertaken in this article because it would involve an extensive excursion into thermodynamics (*q.v.*).

Equation (6) states that the entropy  $s$  at a given state is equal to the entropy  $s_0$  at an arbitrarily chosen initial state, plus the integral between the two states of the infinitesimal of heat added divided by the absolute temperature at which the heat is added. The term  $\delta Q$  is used instead of the usual  $dQ$  to indicate that the quantity is not an exact differential but an infinitesimal that depends upon the thermodynamic path along which the heat is added. The subscript rev means that the process must be reversible, a thermodynamic term indicating the absence of any dissipative effects, such as friction or turbulence, plus complete thermal, chemical, and mechanical equilibrium throughout the process.

In most steam tables the value of  $s_0$  is arbitrarily taken as zero at 32° F and the corresponding saturation pressure of 0.08854 psia. As in the case of volume, internal energy, and enthalpy, the entropy of saturated liquid and vapour are designated as  $s_f$  and  $s_g$ , respectively. Similarly, in the two-phase region it is equal to

$$s = (1 - x) s_f + x s_g = s_f + x s_{fg}$$

**Mollier Chart.**—A useful tool for engineers is the Mollier chart, in which the enthalpy of steam is plotted opposite its entropy. A sketch of such a chart showing the various regions of importance is presented in fig. 3. This chart shows the general relationship

between pressure, temperature, enthalpy, and entropy for steam. On the left is the saturated liquid line along which values of enthalpy for saturated liquid  $h_f$  can be read. This region is not included in most Mollier charts since it can more accurately be covered with tables. Along the saturated vapour line, values of enthalpy of saturated vapour  $h_g$  can be read. Above this line the enthalpy of superheated vapour is obtainable. In the two-phase region where liquid and vapour coexist and where the temperature depends only on the pressure, the enthalpy can be obtained as a function of pressure and steam quality,  $x$ .

**Tables.**—Our modern knowledge of the properties of steam is largely due to H. L. Callendar of England and, more recently, to Joseph H. Keenan and numerous other investigators. With the help of equations of state and other information, the basis of which is partly theoretical and partly empirical, Callendar and Keenan have rationalized the experimental data and compiled comprehensive tables intended for use by engineers and scientists.

Further research on the properties of steam has been under way on an international scale since 1929 under the guidance of the International Conference on the Properties of Steam. The objective is a more accurate evaluation of the thermodynamic properties of steam over a wider range of pressures and temperatures. The properties are to be formulated and published in a manner suitable for use with modern electronic computers.

(RD. A. BR.)

## II. STEAM ENGINE

A steam engine is a heat engine in which the working substance is steam. By a heat engine is meant a machine for doing mechanical work through the agency of heat: it does this by taking in heat at comparatively high temperature, converting part of the heat into another form of energy, and rejecting the remainder of the heat at a lower temperature. The working substance is the vehicle by which heat is taken in and rejected. In a steam engine heat is added to the working substance in a separate vessel, the boiler, where it is vaporized before being admitted to the engine. In the engine the steam expands under pressure, thereby converting part of the heat energy into work. Finally, the remainder of the heat is rejected, either by allowing the steam to escape to the atmosphere, as in locomotives, or by condensing it in a separate apparatus called a condenser, at comparatively low temperature and pressure. A condenser allows for a greater expansion of the steam, thus materially increasing the quantity of work obtained.

The fraction of heat added that is converted into work by the engine is called the thermal efficiency of the engine. The addition of the condenser, while increasing the efficiency, also complicates the mechanism. It requires a supply of cooling water or some equivalent means of keeping the temperature and pressure low in the condenser by absorbing the heat that the steam rejects during condensation. It also requires a pump or other means of removing the condensed substance together with any air that may leak into the condenser from the surrounding atmosphere. In the case of large power plants, where fuel economy is important, the advantage of a condenser is so great that virtually all engines employed for this kind of service are of the condensing type.

Given the upper limit of temperature at which heat is taken in, the efficiency attained by the engine is determined by the lowness of the temperature at which heat is rejected. Similarly, when the lower limit of temperature at which heat is rejected is assigned, the engine's efficiency is increased by raising the temperature at which the working substance takes in heat. To secure high efficiency there must be a wide range through which the temperature of the working substance falls, as a consequence of expansion within the engine, from the level of temperature at which heat is received to the level at which heat is rejected. Thus in the steam engine the most efficient performance, *i.e.*, the greatest output of work in relation to the heat supplied, is secured by keeping the condenser as cold as the available cooling water will allow, and at the same time using a high boiler pressure, so that the working substance is very hot while it receives heat in the act of changing

from water into steam. For this reason the tendency is always toward higher and higher boiler pressures as the mechanical difficulties of boiler construction and high pressure are overcome.

After conversion into steam the working substance may take in a supplementary supply of heat on its way from the boiler to the engine by passing through a superheater, where its temperature is raised above that of the boiler. A common form of superheater is a group of parallel pipes with their surfaces exposed to hot gases of the boiler furnace.

Steam engines are classified into two general types according to the manner in which the steam does work during its expansion. In the first, or piston-and-cylinder type, the steam, in a confined space, namely the part of the cylinder behind the piston, enlarges the volume of that space by pushing the piston forward. It does work by exerting a static pressure on the moving piston (the movement of the steam itself is of no significance). In the second class, to which belong all kinds of steam turbines, the action is less direct. The pressure of the steam is first employed to set the steam itself into motion, forming a jet or group of jets, the momentum of which causes work to be done on a moving part of the machine, either by the impulsive action of the jet or jets on revolving vanes or by the reaction on revolving guide blades during the formation of the jets, or in some instances by a combination of impulse and reaction. In any turbine the action of the steam is kinetic, in contrast with its static action in an engine of the piston type. In both types there is progressive expansion of the steam from the high pressure and relatively small volume at which it is admitted to the low pressure and relatively very great volume at which it is discharged. The principle already stated, that a large range of temperature and pressure between admission and exhaust is essential to efficiency, applies equally to both types. In practice, the turbine has several advantages over the piston-and-cylinder engine. First, it operates much more smoothly because it avoids the reciprocating motion of pistons and the complications associated with them. Secondly, it is capable of expanding the steam to a much larger volume than could otherwise be achieved, thereby greatly increasing the efficiency of operation. Lastly and most important, it can be built to produce tremendous quantities of power with a unit of relatively small size. Because of these advantages the turbine has become the universally accepted method of generating large quantities of power with steam. (See *TURBINE: Steam Turbines*.)

### A. HISTORY

The *Pneumatica* of Hero of Alexandria (about the 1st century A.D.) described the aeolipile, a primitive steam reaction turbine, which consisted of a hollow globe pivoted so that it could turn on a pair of hollow tubes through which steam was supplied from a cauldron. The steam escaped from the globe to the outside air through two bent pipes facing tangentially in opposite directions at the ends of a diameter perpendicular to the axis. The globe revolved by reaction from the escaping steam. Hero's volume also mentioned another device which may be described as the prototype of the pressure engine. A hollow altar containing air was heated by kindling a fire on it; as the air expanded, its pressure drove some of the water in a vessel below into a hanging bucket, which then descended, opening the doors of a shrine. When the fire was extinguished, the air contracted, the bucket emptied, and the doors closed.

A treatise on pneumatics (1601) by Giovanni Battista della Porta described a somewhat similar apparatus, but with steam for the working substance. Its pressure forced water upward from a separate vessel. He also noted that the condensation of the steam could be used to produce a vacuum and thereby suck water from a lower vessel. This was the fundamental idea for the first commercially successful steam engine developed a century later by Savery.

Meanwhile Edward Somerset, 2nd marquess of Worcester, described in his *Century of Inventions* (1663) a method of raising water by the agency of steam. His description was obscure, and no drawings of the device are extant. It appears to have consisted of a pair of displacement chambers, from each of which alternately

FIG. 4.—EARLY STEAM ENGINES: (A) SAVERY'S ENGINE OF 1698; (B) NEWCOMEN AND CAWLEY ENGINE OF 1705; (C) WATT'S PUMPING ENGINE, 1769.

water was forced, probably by admitting steam from an independent boiler, while the other vessel was allowed to refill.

**1. Savery's Engine.**—The earliest practical steam engine was that of Thomas Savery, who, in 1698, obtained a patent for a water-raising engine (fig. 4A). Steam was admitted to one of the oval vessels A, displacing water, which it drove up through the check valve B. When the vessel A was emptied of water, the supply of steam was stopped, and the steam already there was condensed by allowing a jet of cold water from a cistern above to stream over the outer surface of the vessel. This produced a vacuum and caused water to be sucked up through the pipe C and the valve D. Meanwhile steam had been displacing water from the other vessel and was ready to be condensed there. The valves B and D opened only upward. The supplementary boiler and furnace fed water to the main boiler, both of which were supplied with gauge cocks. Another form of Savery's engine had only one displacement chamber and worked intermittently. Savery's engine marked an inventive advance in practical features as well as in the use of artificial means to condense the steam and in the application of a vacuum to raise water by suction from a level lower than that of the engine. It found considerable employment in pumping mines and in raising water to supply houses and towns, and even to drive waterwheels. Its general use in mines was curtailed by the fact that the height through which it would lift water was limited by the pressure the boiler and vessels could bear. Pressures as high as eight or ten atmospheres were employed—and that, too, without a safety valve—but Savery found it no easy matter to deal with high-pressure steam. Also, there was an enormous waste of fuel from the condensation of steam that took place on the surface of the water and on the sides of the displacement chamber during each operation. In proportion to the work done, the consumption of coal was about 20 times greater than in a modern engine.

Before Savery's engine was displaced by its successor, Newcomen's, it was improved by J. T. Desaguliers, who applied a safety valve (invented by Denis Papin) and substituted condensation by a jet of cold water within the vessel for the surface condensation used by Savery. To Savery is ascribed the first use of the term "horsepower" as a measure of performance.

In 1690 Denis Papin suggested that the condensation of steam should be employed to make a vacuum under a piston previously raised by the expansion of the steam. Papin's was the earliest cylinder-and-piston steam engine, and his plan of using steam later took practical shape in the atmospheric engine of Newcomen. But his scheme was made unworkable because he proposed only one vessel as both boiler and cylinder. A small quantity of water was placed at the bottom of a cylinder and heat was applied. When the piston had risen the fire was removed, the steam was

allowed to cool, and the piston did work in its downstroke under the pressure of the atmosphere. After hearing of Savery's engine in 1705, Papin devised a modified form, with a floating diaphragm or piston on the top of the water to keep the water and steam from direct contact with one another. Papin's engine may be described as a noncondensing single-acting steam pump, with steam cylinder and pump cylinder in one.

**2. Newcomen's Atmospheric Engine.**—While Papin was thus going back from his first notion of a piston engine to Savery's cruder type, a new inventor made the piston engine a practical success by separating the boiler from the cylinder and by using (as Savery had done) artificial means to condense the steam. This was Thomas Newcomen, who in 1705, with his assistant John Cawley, gave the steam engine the form shown in fig. 4B. Steam admitted from the boiler to the cylinder by opening a valve allowed the piston to be raised by a heavy counterpoise on the other side of the beam. Then the steam valve was closed, and a jet of cold water entered the cylinder and condensed the steam. The piston was consequently forced down by the pressure of the atmosphere and did work on the pump. The next entry of steam expelled the condensed water from the cylinder through an exhaust valve, and the piston was kept tight by a layer of water on its upper surface. Condensation was at first effected by cooling the outside of the cylinder, but an accidental leakage of the packing water past the piston showed the advantage of condensing by a jet of injection water, and this plan took the place of surface condensation. The engine used steam whose pressure was little if at all greater than that of the atmosphere.

About 1711 Newcomen's engine began to be introduced for pumping mines. It is doubtful whether the action was originally automatic or whether it depended on the periodical turning of taps by an attendant. By 1725 the engine was in common use in collieries, and it held its place without material change for about three-quarters of a century. Near the close of its career Newcomen's engine was much improved in its mechanical details by James Smeaton, who built many large engines of this type about the year 1770.

Compared with Savery's engine, Newcomen's had (as a pumping engine) the great advantage that the intensity of pressure the pumps was not in any way limited by the pressure of the steam. It shared with Savery's, in a scarcely less degree, the defect already pointed out, that steam was wasted by the alternate heating and cooling of the vessel into which it was led. Though obviously capable of more extended uses, it was almost exclusively employed to raise water—in some instances for the purpose of turning waterwheels to drive other machinery.

**3. Watt's Engines.**—James Watt (q.v.), an instrument maker

in Glasgow, Scot., while engaged by the university in repairing a model of Newcomen's engine, was struck with the waste of steam to which the alternate chilling and heating of the cylinder gave rise. He saw that the remedy would lie in keeping the cylinder as hot as the steam that entered it. With this view he added to the engine a new organ—namely the “separate condenser”—an empty vessel separate from the cylinder, into which the steam should be allowed to escape from the cylinder, to be condensed there by the application of cold water either outside or as a jet. To preserve the vacuum in his condenser he added an air pump that would extract the condensed steam and water of condensation, as well as any air that might come in by leakage or by solution in the steam or the injection water. Then, as the cylinder was no longer used as a condenser, he was able to keep it hot by insulating it and providing a steam jacket—a layer of hot steam between the cylinder and an external casing. Further and still with the same object, he covered the top of the cylinder, taking the piston rod out through a steamtight gland, or stuffing box, and allowed steam instead of air to press upon the piston's upper surface. After much experiment Watt patented his improvements in 1769.

Highly important as Watt's first inventions were, they resulted for a time in nothing more than a greatly improved engine of the Newcomen type, much less wasteful of fuel and able to make faster strokes but still only suitable for pumping, still single-acting, with steam admitted during the whole stroke, the piston, as before, pulling the beam by a chain working on a circular arc. The condenser was generally worked by injection, but Watt has left a model of a surface condenser made up of small tubes, in every essential respect like the condensers now used.

Fig. 4C is an example of the Watt pumping engine of this period. Although the top of the cylinder is closed, and steam has access to the upper side of the piston, this is done only to keep the cylinder and piston warm. The engine is still single-acting; the steam on the upper side merely plays the part which was played in Newcomen's engine by the atmosphere; and only the lower end of the cylinder is put in communication with the condenser. There are three valves: the steam valve, the equilibrium valve, and the exhaust valve. At the beginning of the downstroke, the exhaust valve is opened to produce a vacuum below the piston, and the steam valve is opened to admit steam above it. At the end of the downstroke, the steam valve and the exhaust valve are shut, and the equilibrium valve is opened. This puts the two sides in equilibrium and allows the piston to be pulled up by the pump rod, which is heavy enough to serve as a counterpoise. A vacuum is maintained in the condenser by an air pump, which extracts water, steam, and air from the condenser and then discharges the contents into the hot well, from which water for the feed pump is drawn.

In a second patent (1781) Watt described the sun-and-planet wheels and other methods of making the engine give continuous revolving motion to a shaft provided with a flywheel. The crank and connecting rod—already a familiar mechanical device from its use on the treadle of a lathe—would have been the natural means of doing this, but its application to the steam engine had been made the subject of a patent by James Pickard, and Watt, rather than coming to terms with Pickard, whom he regarded as a plagiarist of his own ideas, made use of his sun-and-planet motion until the patent on Pickard's crank expired. The reciprocating motion of earlier forms had served only for pumping; by making the steam engine drive a revolving shaft, Watt opened up many other channels of usefulness. The engine was still single-acting, the connecting rod was attached to the far end of the beam; and that carried a counterpoise which served to raise the piston when steam was admitted below it.

In 1782 Watt patented two further improvements of great importance, both of which he had invented some years before. One was the use of double action; i.e., the application of steam and vacuum to each side of the piston alternately. The other (invented as early as 1769) was the use of the steam's expansion. With this arrangement, which was essential to economy of fuel, admission of steam to the cylinder was stopped when the piston had made only a part of its stroke, thus allowing the rest of the

stroke to be performed by the expansion of the steam already in the cylinder. To let the piston push as well as pull the end of the beam, Watt devised his so-called parallel motion, an arrangement of links connecting the piston-rod head with the beam in such a way as to guide the rod to move in a very nearly straight line. He further added a throttle valve for regulating the rate of admission of steam and a centrifugal governor, in the form of a double conical pendulum, which controlled the speed by a throttle valve.

Among other important devices associated with Watt was the indicator, by which diagrams showing the relation of the steam pressure in the cylinder to the movement of the piston are automatically drawn. Its invention seems to have been mainly due to his assistant John Southern.

In partnership with Matthew Boulton in Birmingham, Eng., Watt manufactured and sold his engines with great success and held the field against all rivals in spite of severe assaults on the validity of his patents. Notwithstanding the advantage to be gained by using steam expansion, he continued to employ only low pressures—seldom more than 7 psi (pounds per square inch) over that of the atmosphere. His boilers were fed, as Newcomen's had been, through an open pipe rising high enough to let the column of water in it balance the pressure of the steam. He gave a definite numerical significance to the term “horsepower,” defining it as the rate at which work is done when 33,000 lb. are raised one foot in one minute.

Although Watt's first patent described a noncondensing engine that would have required steam of a higher pressure, he did not pursue this idea, perhaps because as early as 1725 a noncondensing engine had been described by Jacob Leupold in his *Theatrum machinarum*.

It was not until much later that the thermodynamic principles underlying the action of the steam engine came to be understood. Engineers were consequently slow to appreciate the fact that to obtain fuel economy it was advantageous to employ a high initial pressure, in combination with much expansion in the cylinder and with the separate condenser of Watt.

**4. Trevithick, Bull, and Evans.**—The introduction of the noncondensing and, at that time, relatively high-pressure engine was effected in England by Richard Trevithick about 1798 and in the U.S. by Oliver Evans about 1800. Both Evans and Trevithick applied their engines to propel carriages on roads, and both used for the boiler a cylindrical vessel with a cylindrical flue inside containing the fire—the construction now known as the Cornish boiler. In association with Edward Bull, Trevithick had previously made direct-acting pumping engines, with an inverted cylinder set over and in line with the pump rod, thus dispensing with the beam that had been a feature in all earlier forms. But in these Bull engines, as they were called, the steam was condensed by a jet of cold water in the exhaust pipe, and Boulton and Watt successfully opposed them as infringing Watt's patent. To Trevithick belongs the honour of being the first to use a steam carriage on a railway; in 1804 he built a locomotive to run on what had formerly been a horsecar route, in Wales. It may be added that as early as 1769 a steam carriage for roads had been built in France by Nicholas Joseph Cugnot, who used a pair of single-acting high-pressure cylinders to turn a driving axle by means of pawls and ratchet wheels. To the initiative of Evans may be ascribed the early general use of high-pressure steam in the United States, a feature which for many years distinguished American from English practice. (See RAILWAY: Locomotives.)

**5. Compound Engine and Cornish Engine.**—Among contemporaries of Watt the name of Jonathan Hornblower deserves special mention. In 1781 he constructed and patented what would now be called a compound engine, with two cylinders of different sizes. Steam was first admitted into the smaller cylinder and then passed over into the larger, doing work against a piston in each. The two cylinders were placed side by side, and both pistons worked on the same end of a beam overhead. This was an instance of the expansive force of steam and as such was earlier than the patent, though not earlier than the invention of expansive working by Watt. Hornblower lost a patent suit to the Birmingham firm

for infringing their patent in the use of a separate condenser and air pump. However, the compound engine was revived in 1804 by Arthur Woolf, with whose name it is often associated. By using steam of fairly high pressure and cutting off the supply before the end of the stroke in the small cylinder, Woolf expanded the steam to several times its original volume. Mechanically the two-cylinder compound engine has some advantage over a one-cylinder engine with the same amount of expansion, in exerting a more uniform driving effort. But another and more important advantage lies in the fact that by dividing the whole range of expansion into two parts the cylinders in which these are separately performed are subject to a reduced range of fluctuation in their temperature. This helps to limit a source of waste present in all piston engines, namely the waste resulting from the heating and cooling of the metal by its alternate contact with hot and cooler steam. The introduction of compound expansion formed the most outstanding improvement that steam engines of the piston-and-cylinder type had undergone since the time of Watt.

Woolf introduced the compound engine about 1814 as a pumping engine in the mines of Cornwall, Eng., but it met a strong competitor in the high-pressure single-cylinder engine of Trevithick, which had the advantage of greater simplicity in construction. Woolf's engine fell into comparative disuse, and the single-cylinder type took a form which, under the name of the Cornish pumping engine, was for many years famous for its great fuel economy. In this engine the cylinder was set under one end of a beam, and from the other end hung a heavy rod that operated a pump at the foot of the shaft. Steam was admitted above the piston for a short portion of the stroke, thereby raising the pump rod, and was allowed to expand for the remainder of the stroke. An equilibrium valve connecting the space above and below the piston, as in fig. 4C, was then opened, and the pump rod descended, doing work in the pump and raising the engine piston. The large mass that had to be started and stopped at each stroke served by its inertia to counterbalance the unequal pressure of the steam, for the ascending rods stored up energy of motion in the early part of the stroke, when the steam pressure was greatest, and gave out energy in the later part, when the pressure was much lowered by expansion. The frequency of the stroke was controlled by a device called a cataract, consisting of a small plunger pump, in which the plunger, raised at each stroke by the engine, was allowed to descend more or less slowly by the escape of fluid below it through an adjustable orifice. In its descent it liberated catches that held the steam and exhaust valves from opening. A similar device controlled the equilibrium valve; it could be set to pause at the end of the piston's downstroke so that the pump cylinder might have time to become filled.

The final revival of the compound engine did not occur until about the mid-19th century, and then several agencies combined to effect it. In 1845 John M'Naught introduced a plan to improve beam engines of the original Watt type by adding a high-pressure cylinder whose piston acted on the beam between the centre and the flywheel end. Steam of higher pressure than had formerly been used, after doing work in the new cylinder, passed into the old or low-pressure cylinder, where it was further expanded. Many engines with insufficient power for the extended machinery they had to drive were "M'Naughted" in this way and after conversion were found not only to yield more power but to show a marked economy of fuel. The compound form was selected by William Pole for the pumping engines of Lambeth, Eng., and other waterworks about 1850; in 1854 John Elder began to use it in marine engines; in 1857 E. A. Cowper added a steam-jacketed intermediate reservoir for steam between the high- and low-pressure cylinders, which made it unnecessary for the stroke of the low-pressure piston to be just beginning when that of the other piston was just ending. As facilities increased for the use of high-pressure steam, compound expansion came into more general use, its advantage becoming more conspicuous with every increase in boiler pressure. In marine practice, where economy of fuel was an obviously important factor in design, the principle of compound expansion was extended by the introduction of triple- and even quadruple-expansion engines.

**6. Application to Locomotives and Steamboats.**—The adaptation of the steam engine to railways, begun by Trevithick, became a success in the hands of George Stephenson, whose engine, the "Rocket," when tried along with others in 1829, outshone its competitors. The principal features of the "Rocket" were an improved steam blast for urging the combustion of coal and a boiler (suggested by Henry Booth) in which a large heating surface was provided by the use of many small tubes through which the hot gases passed. Further, the cylinders, instead of being vertical as in earlier locomotives, were set at a slope, but later altered to a position more nearly horizontal. To these features was added later the link motion, a contrivance that enabled the engine to be easily reversed and the amount of expansion to be readily varied. In the hands of George Stephenson and his son Robert, the locomotive took a form that in the main was retained by the far heavier locomotives later in use.

The first practical steamboat was the tug "Charlotte Dundas," built by William Symington and tried in the Forth and Clyde Canal in 1802. A Watt double-acting condensing engine, placed horizontally, acted directly by a connecting rod on the crank of a shaft at the stern, which carried a revolving paddle wheel. The trial was successful, but steam towing was abandoned for fear of injuring the banks of the canal. Ten years later Henry Bell built the "Comet," with side paddle wheels, which ran as a passenger steamer on the Clyde; but an earlier inventor to follow up Symington's success was Robert Fulton of the U.S. After successful experiments on the Seine, he fitted a steamer on the Hudson River in 1807 with engines made to his designs by Boulton and Watt and brought steam navigation for the first time to commercial success.

**7. Rise in Steam Pressure and Piston Speed.**—With improvements in the details of design and construction it gradually became practicable to use higher steam pressures and piston speeds and consequently to obtain not only greater efficiency but also a greater amount of power from engines of given bulk. The triple-expansion engine, introduced by A. C. Kirk in 1874, did not come into general use until after 1881. It became the normal type of marine engine, with pressures generally ranging from 150 to 200 psi, piston speeds generally of 500 or 600 ft. per minute (but sometimes as high as 900 or 1,000), and coal consumption of about 1½ lb. per hour per indicated horsepower. The triple-expansion engine continues to be largely used in steamships that are not driven by turbines. In some instances quadruple expansion has been preferred, with somewhat higher pressures, but when the pressure is raised too greatly it has been the practice to abandon the piston engine in favour of the steam turbine. The gigantic concentration of steam power found in a great steamship or at a power station has been made practicable only by the introduction of the turbine. The introduction of turbines in 1907 as the motive engines of the "Lusitania" and "Mauretania" constituted a new departure in steam engineering. It was then a novelty to develop roughly 70,000 hp. in the engine room of a single ship.

**8. Introduction of the Steam Turbine.**—The invention of the steam turbine revolutionized marine engine practice with respect to the largest and fastest vessels. For the generation of electricity the turbine has a notable advantage in directly developing the high speed of rotation required by electric generators. Its large sizes their efficiency is unrivaled by steam engines of any kind. To Sir Charles Parsons is owed not only the main idea of the modern steam turbine, but also the invention of many mechanical features and details essential to its practical success and general adaptation.

In the steam turbine, pressure, instead of being exerted on a piston, is employed to set the fluid itself in motion. There is a conversion of pressure energy into velocity energy as a preliminary step toward obtaining the effective work of the machine. If this were done in a single step it would involve immensely high velocities in the steam jet and in the vanes on which the jet acts. Attempts to design a steam turbine were made by numerous inventors, but they fell short of practical success mainly because of the difficulty of arranging for high enough velocity in the working parts to utilize a reasonably large fraction of the kinetic energy.

of the steam. There was a further difficulty in getting the energy of the stream into a suitable kinetic form, namely, to get the stream of issuing particles to take a single direction, without undue dispersion, when steam was allowed to expand through an orifice from a chamber at high pressure into a space where the pressure was much lower.

In 1889 Carl Gustaf de Laval introduced a form of steam turbine in which both of these difficulties were considerably overcome, partly by the special form of the nozzle used to produce the steam jet and partly by design features that allowed an exceptionally high speed to be reached in the wheel carrying the vanes against which the steam impinged.

Parsons attacked the problem at an earlier date and in a different way by his invention of the multistage turbine. He divided the whole expansion of the steam into a great number of successive and separate steps and thereby limited the velocity acquired at each step to such an extent as to make it comparatively easy to extract the greater part of the kinetic energy as work done upon the moving blades, without making the velocity of these blades inconveniently high. Moreover, in Parsons' compound turbine the range of pressure through which the steam expands in each step is too small to cause any difficulty in the formation of the jets. The guide blades, which form the jets, are distributed around the circumference of the revolving wheel, and all the revolving blades are consequently in action at once. The steam flows from end to end of the turbine through an annular space between a revolving drum and the casing that surrounds it. Parallel rings of fixed guide blades project inward from the casing at suitable distances, and between these are rings of moving blades that project outward from the drum and revolve with it. At each step in the expansion the steam passes through a ring of fixed guide blades, and the streams so formed impinge on the next ring of moving blades, and so on. The construction, which is of great simplicity, is described, along with others, in the article *TURBINE*. The turbine lends itself well to the generation of power on a large scale, especially where a fairly high speed of rotation is desired.

Parsons introduced his multistage steam turbine in 1884. For some years it was made in small sizes only, and the steam was discharged to the atmosphere without condensation. So long as this was done the steam turbine was sacrificing one of its most important advantages, namely, its exceptional capacity for utilizing the energy of low-pressure steam down to the lowest vacuum obtainable in a condenser. In 1891 it was first fitted with a condenser, and it then began to be used in electric generating stations. The first application to marine propulsion was in the "Turbinia" in 1897. The success of this little experimental vessel of 100 tons, which, with its horsepower of 2,100, made what was then a record in speed for any ship, was soon followed by the application of the turbine to warships and other steamers. In merchant vessels its use was at first limited to those of the highest speed, for the turbine shaft was directly coupled to the shaft of the screw propeller. But in 1910 Parsons introduced a mechanical reducing gear between the two that allowed the turbine shaft to run much faster than the propeller shaft, to the great advantage in efficiency of both turbine and propeller. Later he followed this up by a double-reduction gearing that allowed a still greater difference in speed of rotation between the propeller and the turbine. In most ships the single-reduction system is sufficient for the purpose, and its introduction greatly extended the range within which the turbine could be advantageously substituted for the three-cylinder or four-cylinder compound engine of the piston type in oceangoing steamships.

**9. Early Theory.**—In the early development of the steam engine inventors had little in the way of theory to guide them. Watt had the advantage of a knowledge of Joseph Black's doctrine of latent heat, but there was no philosophy of the relation of work to heat until long after the inventions of Watt were complete. The theory of the steam engine as a heat engine may be said to date from 1824, when N. L. Sadi Carnot published his *Réflexions sur la puissance motrice du feu et sur les machines propres à développer cette puissance*, a remarkable essay in which he showed that heat does work only in the process of descent from a higher to a lower temperature. But Carnot was not then aware that any of

the heat disappears in the process, and it was not until the doctrine of the conservation of energy was established in 1843 by the experiments of James Prescott Joule that the theory of heat engines began a vigorous growth. From 1849 onward the science of thermodynamics was developed with extraordinary rapidity by Rudolf Clausius, W. J. Rankine, and William Thomson (Lord Kelvin) and was applied, especially by Rankine, to practical problems in the use of steam. Rankine's *Manual of the Steam Engine*, published in 1859, was the first attempt at a systematic treatment of steam-engine theory. It involved the assumption that the cylinder and piston might be treated as behaving to the steam like nonconducting bodies, in other words, that the transfer of heat between the steam and the metal might generally be disregarded. One effect of this was to treat the volume of steam consumed per stroke as corresponding to the volume of the cylinder up to the point of cutoff. When steam enters the engine cylinder, it finds the metal chilled by the previous exhaust, and a portion of it is at once condensed. This has the effect of increasing, often very largely, the volume of steam required per stroke. As expansion goes on, the water that was condensed during admission begins to be reevaporated, and this action is often prolonged into the exhaust. It is now recognized that exchanges of heat between the steam and its metal envelope cannot be ignored.

## B. ACTION OF RECIPROCATING ENGINES

Most reciprocating engines are double-acting; *i.e.*, steam from the boiler is alternately admitted to each side of the piston. In each double stroke, or revolution, there are four events for each end of the cylinder: (1) admission, which begins by opening a steam valve when the piston is at or very near the limit of its travel; (2) cutoff, at which the steam valve is closed and admission ceases. This may take place early in the stroke. The steam enclosed behind the piston then expands, with falling pressure, while the stroke continues, until (3) release occurs when an exhaust valve opens, allowing the steam to escape from the cylinder. Its discharge generally continues for a large part of the backstroke, until (4) the exhaust valve closes and compression begins. From there to the end of the backstroke, the steam remaining in the cylinder is compressed into the clearance space behind the piston. This compression of the residue of steam, called cushioning, assists smoothness of working as the piston passes what is called the dead point, at the limit of its stroke. The cushioning effect is often augmented by giving the steam valve lead; *i.e.*, causing it to open a little before the piston reaches the dead point.

**1. Distribution of Steam.**—Together, these various events of the stroke constitute what is termed the distribution of the steam. They are conveniently exhibited by drawing an indicator diagram of the action, such as that illustrated in fig. 5. There, on a base PQ, which represents the stroke, lines are drawn to show the continuous changes of pressure that go on within the cylinder during the whole action. Starting from the beginning of the stroke at a, for one side of the piston, steam is admitted up to the cutoff point b. At (or near) the end of the forward stroke c, the steam is allowed to escape. Compression, in the return stroke, begins at d. From b to c the steam confined in the cylinder is expanding, with falling pressure, doing work on the piston. The whole work done in the revolution, namely the average of the force acting on the piston and the distance through which it moves, is represented by the enclosed area of the indicator diagram, a-b-c-d.

The diagram is idealized in the sense that the events are shown as if they happened suddenly, giving sharply defined changes from admission to expansion and so on. In any real engine the events are necessarily gradual, for no valve—whatever its type—can close or open instantaneously.

A real indicator diagram accordingly has a smoother outline with rounded corners to mark the places of cutoff, release, compression, and admission. In

FIG. 5.—INDICATOR DIAGRAM SHOWING DISTRIBUTION OF STEAM (see TEXT FOR FURTHER INFORMATION)

practice, release always occurs before the piston has quite completed its stroke.

The distance PQ, which represents the stroke, may be interpreted as a volume, namely the volume swept through by the piston, and a point O behind P may be so taken that OP represents, on the same scale, the volume of the clearance. The distance measured horizontally from the line OY to any point of the curve represents the whole volume of steam behind the piston at that point, and the curve between admission and release exhibits the relation of the pressure to the total volume of the steam enclosed behind the piston throughout its process of expansion.

Actual indicator diagrams may be automatically drawn by attaching to the cylinder of the engine a device in which a pencil is made to rise or fall proportionally to the variations of steam pressure, while a paper, on which it inscribes a record, moves back and forth horizontally through distances proportional to the movement of the engine piston. Many forms of indicator have been designed to give a diagram in which the coordinates represent respectively the displacement of the piston and the pressure of the steam against it. From such diagrams it is easy to infer the mean effective pressure throughout the stroke and also to observe how the valves are working. By connecting the instrument successively to each of the two ends of the cylinder in a double-acting engine a complete record is obtained for the two strokes that make up a revolution. The indicated horsepower (ihp) is determined by the formula

$$\text{ihp} = \frac{nL(p_1A_1 + p_2A_2)}{33,000}$$

where  $A_1$  and  $A_2$  are the areas of the two sides of the piston, in square inches;  $p_1$  and  $p_2$  are the mean effective pressures on the two sides, in pounds per square inch, as determined from the diagrams;  $n$  is the number of revolutions per minute, and  $L$  is the stroke in feet. In steam engine trials such diagrams are taken during a considerable period. The amount and condition of the steam passing through the engine is observed by measuring either the quantity of water discharged from the condenser (if of the surface type) or the quantity of feed water required by the boiler to keep the water level constant. From these data it is possible to compare the power developed with the heat supplied. Measurements of the heat rejected may also be made by observing the quantity of condensing water used and its rise in temperature; together these figures give material for drawing up a balance sheet of the disposal of thermal energy.

**2. The Slide Valve.**—The admission and exhaust of steam, for each end of the cylinder, may be controlled by separate valves, but very commonly a single moving piece, called a slide valve, serves to control the events for both ends. A common form of the slide valve is illustrated in section in fig. 6, which also shows

FIG. 6.—CROSS SECTION OF A SLIDE VALVE SHOWING THE EXHAUST AND INLET PORTS BELOW IT, AND CYLINDER AND PISTON

the cylinder, with the piston, and the steam ports and passages leading to each end of the cylinder. The face on which the valve slides is a plane surface on one side of the cylinder with three ports or openings extending across the greater part of the cylinder's width. The central opening is the exhaust port through which the steam escapes after doing its duty in the cylinder. The others, which are narrower, lead to the two ends. The valve itself is a box-shaped cover, sliding on the face, and contained in the valve chest, or chamber, to which steam is admitted from the boiler. When the valve moves a sufficient distance to either side of the middle

position, steam is admitted to one end of the cylinder, past the outer edge. Similarly steam escapes from the other end of the cylinder, through the cavity of the valve, to the exhaust port. The valve takes its motion from an eccentric on the engine shaft, which is set more than 90° ahead of the crank, so that the valve has already begun to uncover the port on one side when the piston is at the corresponding dead point, with the result that steam passes from the steam chest above the valve into the space behind the piston. Fig. 7 shows a slide valve in its middle position and illustrates the internal lap  $i$  and the external lap  $e$  which the valve

FIG. 7.—CROSS SECTION OF SLIDE VALVE IN MIDDLE POSITION: (i) INTERNAL LAP. (e) EXTERNAL LAP

must have to make expansive working possible. At the beginning of the stroke it has already passed its middle position by an amount at least equal to  $e$ , so that steam may enter. It continues to move farther, opening the port more widely, and then begins to return, while the piston is still advancing in the cylinder. At a particular point in its return the outer edge of the valve closes the port; this determines the instant of cutoff. The piston continues to advance, with expansion of the steam confined in the cylinder, while the valve continues to move back, until its inner edge begins to uncover the port, allowing steam from the cylinder to escape to the exhaust channel. This point, which depends on the internal lap  $i$ , determines the instant of release. The port then opens more widely to exhaust and remains open during most of the backstroke of the piston until the valve, again moving in the original direction, brings its inner edge again over the port, and compression begins. Similar events for the other end of the cylinder are determined by the other side of the valve. The positions of the piston when the several events occur depend on the amounts of the laps  $e$  and  $i$  and of the angular advance that exceeds 90° in the angle by which the eccentric stands ahead of the crank. If there were no laps and no angular advance, steam would be admitted during the whole forward stroke and exhausted during the whole backward stroke. By giving the valve laps and angular advance, expansive working becomes possible. The slide valve, however, is not too well adapted to effect a cutoff early in the stroke, and, when much expansion is desired, a separate expansion valve is added, or valves of a different type are used to control the distribution of the steam.

In many engines the events are controlled by using, at each end of the cylinder, separate valves for admission and exhaust (fig. 8). Sometimes these are double-beat drop valves in the sense that the valve, when it drops into its seat, simultaneously closes two passages. These are so arranged that the steam pressure tending to close or open the valve remains balanced, and no large force has to be exerted. Such

FIG. 8.—CROSS SECTION OF ONE END OF A CYLINDER SHOWING DROP VALVES

valves are often worked by cams and levers from a lay shaft alongside the cylinder and driven from the main shaft so as to turn in unison. Sometimes the admission valves are closed by a tripping device that is connected to the governor of the engine in such a manner that the cutoff comes earlier or later when the speed exceeds or falls short of the normal. Thus the engine automatically adjusts the amount of power it develops to suit changes in the demand made upon it by the mechanism which it drives.

Fig. 6 shows a slide valve form usual in locomotives and small engines, but in large sizes the unbalanced pressure of steam on the back of the valve would cause much friction and wear in the movement of the valve sliding over the working face. In large engines, such as those of steamships, it is usual to relieve the pressure of the valve on the working face by fitting the back of the valve with a relief frame, extending between the valve and the steam-chest cover, in order to prevent the steam of the steam chest from having access to the whole back surface of the valve.

Frequently used as a substitute for the flat form of slide valve is a piston form in which the effective sliding portions of the valve extend all around the surface of a cylinder and slide over cylindrical fixtures in the valve chest, around which the steam ports extend.

**3. Reversing Gears.**—The slide valve is a particularly convenient means of controlling the admission of steam when, as in locomotives or marine engines, etc., the engine's direction of motion must frequently be reversed. It is only necessary to provide means by which the valve may be actuated by either of two eccentrics, one set at the angle suitable for forward running and the other at the angle suitable for backward running.

In Stephenson's link motion, shown in fig. 9A, the engine shaft carries two eccentrics, one of which is set ahead of the crank at a suitable angle for one direction of running and the other at a suitable angle for the other direction. Their rods are connected to the ends of a link which gives its name to the contrivance. The link, a slotted bar curved to a circular arc, is capable of being moved up or down, being suspended from a rod that can be raised or lowered by means of the hand lever above. The valve rod ends in a block that slides within the link. This device allows either the forward eccentric or the backward eccentric to determine the motion of the valve and so allows the engine to be reversed. Moreover, if the link is set to an intermediate position, in which it takes its motion chiefly from one eccentric but partly from the other, the valve receives a motion virtually the same as that which it would get from a single eccentric of shorter travel and greater angular advance. The effect is to give a distribution of steam in which the cutoff is hastened and the expansion and compression are increased.

Thus besides allowing full forward and full backward gear the link may be notched up to give a much shorter admission of steam along with more compression, a matter of practical value in running a locomotive, where frequent large variations in the demand for driving effort have to be met.

Various other forms of link motion have been devised that share this advantage. It is also shared by a group of equivalent mechanical devices, called radial valve gears, in which only one eccentric is employed, but the valve can be moved and varied in the same way. Of these the most widely used is the Walschaerts gear, very common in locomotives, a diagram of which is shown in fig. 9B. There A is a projection moving with the engine piston. The valve V takes motion partly from it, through the rods AB and BV; but BV has a fulcrum at D, the position of which varies through the movement of the rod DG. That rod is supported by a suspension rod J, and its end at G can slide in a link HI rocking about a fixed fulcrum at O. There is one eccentric, CF, set at right angles to the crank CK, and giving motion to the rocking link HI by the rod FH. The block G can be shifted from near H to I by raising the suspension rod J. This reverses the motion and allows also for notching up to any intermediate position.

**4. Governors.**—To keep a steam engine running at a uniform speed, notwithstanding variations in the demand for power, an automatic regulator, or governor, is provided. Regulation may be effected in two ways: the steam may be throttled more or less on

FIG. 9.—(A) STEPHENSON'S LINK MOTION; (B) WALSCHAERTS GEAR

its way from the boiler to the engine, so that the pressure of admission is reduced when the speed tends to rise and increased when the speed tends to fall; or the point of cutoff may be varied, with the result of admitting a greater or smaller volume of steam in each stroke. In small engines the governor often acts on a throttle valve, but for high-efficiency engines it is preferable to govern by altering the cutoff. In such engines an early cutoff is employed to secure a proper amount of expansion, and a small change in the position of the cutoff largely affects the amount of steam admitted and consequently the amount of work done.

Watt's original governor consisted of a pair of balls revolving about a vertical spindle as conical pendulums under the combined effect of their own weight and the centrifugal force due to their speed of revolution. Any increase of speed sufficient to overcome the slight friction of the attached gearing made them take up a higher position, and in so doing they partially closed a throttle valve. This went on until, at a slightly greater speed than before, equilibrium was established between the supply of steam and the demand for power. Here, as in all governors, the effect is not to maintain a strictly constant speed, but to prevent the variation, either way, from exceeding narrow limits.

In modern governors the centrifugal force of the balls generally acts not simply against their own weight, but against an extra load or against the force of a spring.

In many factory and other engines the governor determines the position of cutoff by means of a trigger action of the type already mentioned, in which the admission valve, which has been opened and held open by a cam turning with the engine shaft, is suddenly disconnected by the release of a trigger at a point depending on the exact height of the governor balls.

**5. The Flywheel.**—The function of the governor is, generally, to keep the engine running at a nearly uniform rate, measured in revolutions per minute; the function of the flywheel is to keep the rate nearly uniform within the limits of any one revolution. For this purpose it must act as a reservoir of energy, alternately storing and restoring the excess amounts that result from periodic variations of turning moment in the operation of the piston on the crank. At the dead points the piston's rate of doing work is zero, and it rises to a maximum at an intermediate point, the position of which may be much affected by an early cutoff. The flywheel is drawn upon for energy during those parts of the revolution in which the work done by the piston (or pistons) on the engine shaft is less than the work done by the shaft on the mechanism driven by the engine, and it takes up the surplus during the other parts of the revolution. To effect this alternate give and take of energy the flywheel must undergo small variations of speed, the magnitude of which may be kept down to any assigned amount by giving the rim a sufficient mass and speed.

**6. Inertia of Reciprocating Parts.**—The effective effort on the crank is greatly influenced, especially in high-speed engines, by

the inertia of the piston, piston rod, and connecting rod. At the beginning of the stroke, when the piston is coming toward the crankshaft, these reciprocating masses are acquiring motion; from a point near the middle to the end of the stroke they are losing motion. Hence in the early part the effort on the crank is reduced below what is due to the steam pressure on the piston and in the later part it is increased. In a high-speed engine the forces due to acceleration become so large as seriously to affect questions of design.

In direct-acting steam pumps the inertia of pump rods and buckets forms an additional item in the consideration of reciprocating mass; its effect is generally beneficial in tending to equalize the force exerted on the pump throughout the stroke.

Another aspect of the acceleration of reciprocating parts is its effect on the balance of the engine as a whole. This is especially important in locomotives and marine engines. In a locomotive the forces on the engine frame arising from the inertia of the pistons and rods tend to make the engine sway laterally; this is to some extent prevented by placing balance masses on the wheels. But such masses, although they may be adjusted nearly to balance the horizontal forces, introduce unbalanced vertical forces, causing what is called hammerblow. In extreme cases these vertical forces might even lift the wheels from the rails. Short of that, however, they are objectionable in causing periodic variations in the pressure on the rails, which tend to set bridges into oscillation and may add substantially to the stresses for which the railway engineer must provide.

### C. TYPES OF RECIPROCATING ENGINES

In classifying engines with regard to their general arrangement of parts and mode of working, account has to be taken of a considerable number of independent characteristics. There is first a general division into condensing and noncondensing engines, with a subdivision of condensing class into those acting by surface condensation and those using injection. Next there is the division into compound and noncompound, with a further classification of the former as double-, triple-, or quadruple-expansion engines. Again, engines may be classed as single- or double-acting, according to whether the steam acts on one or alternately on both sides of the piston. Also, a few engines—such as steam hammers and certain kinds of steam pumps—are nonrotative, *i.e.*, the reciprocating motion of the piston does work simply on a reciprocating piece, but generally an engine does work on a continuously revolving shaft. In most cases the crankpin of the revolving shaft is connected directly with the piston rod by a connecting rod, and the engine is then said to be direct-acting; in other cases, of which the beam engine is an historical example, a lever is interposed between the piston and the connecting rod. The same distinction applies to nonrotative pumping engines, in some of which the pis-

ton acts directly on the pump rod, while in others it acts through a beam. The position of the cylinder is another element of classification, giving horizontal-, vertical-, and inclined-cylinder engines. In most vertical engines the cylinder is above the connecting rod and crank. In oscillating-cylinder engines (a type still found in some riverboats) the connecting rod is dispensed with; the piston rod works on the crankpin, and the cylinder oscillates on trunnions to allow the piston rod to follow the crankpin around its circular path. In rotary engines there is no piston in the ordinary sense; the steam does work on a revolving piece, thus avoiding the need to later convert reciprocating into rotary motion.

**1. Beam Engines.**—In Newcomen's single-acting atmospheric engine the beam was a necessary feature; the use of water packing for the piston required that the piston should move down in the working stroke, and a beam was needed to let the counterpoise pull the piston up. Watt's improvements eliminated the need for the beam, and in one of the forms he designed it was discarded—namely, in the form of a pumping engine known as the Bull engine, in which a vertical inverted cylinder stands over and acts directly on the pump rod. However, the beam formed a convenient driver for pump rods and valve rods, and the parallel motion invented by Watt as a means of guiding the piston rod, which could easily be applied to a beam engine, was, in the early days of engine building, an easier thing to construct than the plane surfaces which are the natural guides of the piston rod in a direct-acting engine. In modern practice the direct-acting type has almost wholly displaced the beam engine.

**2. Direct-Acting Engines.**—Of direct-acting engines the horizontal arrangement has in general the advantage of greater accessibility, but the vertical arrangement saves floor space. In small forms the engine is generally self-contained, that is, a single frame or bedplate carries all the parts, including the main bearings in which the crankshaft with its flywheel turns. The frame often takes a girder shape, which brings a portion of it into a favourable position for taking the thrust between the cylinder and the crankshaft bearings and allows two surfaces to be formed on the frame to serve as guides for the crosshead. When a condenser is used with a horizontal engine it is often placed behind the cylinder, and the air pump, which may be within the condenser, has a horizontal plunger or piston on a tail rod or continuation of the main piston rod through the back cover of the cylinder. In large horizontal engines the condenser generally is in a well below, and its pump is driven by a mechanism linked with the crosshead.

**3. Coupled Engines.**—When uniformity of driving effort or the absence of dead points is important, two independent cylinders often work on the same shaft by cranks at right angles to each other. Such engines can start readily from any position. In some engines three cylinders, set to work on cranks  $120^\circ$  apart, cooperate in giving a still more uniform drive.

FIG. 10.—UNIFLOW ENGINE IN WHICH THE PISTON ACTS AS EXHAUST VALVE AND THE ADMISSION VALVES ARE IN THE CYLINDER ENDS

Winding engines for mines and collieries, in which ease of starting, stopping, and reversing is essential, are usually made by coupling a pair of cylinders on opposite sides of the winding drum.

**4. Compound Engines.**—Large direct-acting engines are usually compounded either by having a high- and a low-pressure cylinder side by side, with cranks at right angles, or by putting one cylinder behind the other with a common centre line. The latter is called a tandem arrangement. In a tandem engine, since the pistons agree in phase, the steam may expand directly from the small into the large cylinder. But the connecting pipe and steam chest form a receiver of considerable size, and it is preferable to cut off the supply of steam to the large cylinder at an earlier stage of the stroke. For mill engines the compound tandem and compound coupled types of engine are very usual. The high-pressure cylinder is often fitted with some form of trip gear.

The chief advantage of compounding is that it reduces the condensation that hot steam undergoes in the cylinder through contact with metal that has been chilled by the exhaust of the previous stroke. Compound working acts beneficially by narrowing the range through which the temperature periodically fluctuates in the metallic surfaces exposed to contact with the operative steam. The amount of steam that is at once condensed on admission depends on the extent to which the surface with which it comes in contact has been chilled during the previous exhaust. For this reason there is less loss through initial condensation in a compound engine giving the same total ratio of expansion.

**5. Uniflow Engine.**—The periodic give and take of heat between the steam and the metallic surfaces, which is a serious source of loss in any reciprocating engine, can be reduced by having separate valves for admission and exhaust, so that the same port surfaces and valve surfaces are not brought into contact with hot and comparatively cold steam. This idea is carried further in the uniflow engine (fig. 10) by an ingenious arrangement whereby the ends of the cylinder, where the steam is admitted, are always kept hot, the exhaust taking place at the middle of the cylinder through ports in the circumference which are uncovered by the motion of the piston.

The uniflow design is a conspicuously successful departure from earlier practice. It allows high-pressure steam to be expanded in a single cylinder without the drawbacks ordinarily entailed in non-compound operation. There is, however, still enough exchange of heat between the metal and the steam to make superheating highly advantageous.

**6. Condensation.**—In land engines a jet form of condenser is common, but surface condensation is resorted to when the available water supply is unsuited for boiler feed. When there is no large supply of condensing water a very fair vacuum can be obtained by using an evaporative condenser, consisting of a stack of pipes into which the exhaust steam is admitted and over which a small amount of cooling water is allowed to drip. This water is evaporated by the heat which the condensing steam gives up. Such a condenser is placed in the open, generally on a roof where the air has free access. The amount of water it uses need not exceed the amount of steam that is condensed, and it is a small fraction of the amount that would be required in a jet or surface condenser.

**7. High-Speed Direct-Acting Engines.**—Prior to the development of the steam turbine the demand for engines suitable for driving electric generators without the intervention of a belt led to the introduction of various forms of direct-acting engine adapted to run at a high speed. Some of these were single-acting, steam being admitted to one side of the piston only, generally the back, with the result that the rods could be kept in a state of thrust throughout the revolution and alternations of stress in the rods and at the joints thereby avoided, together with the knocking and wear of the bearing brasses. To assure, however, that the connecting rod should always push and never pull against the crankpin there had to be much cushioning during the outstroke because from about the middle of that stroke to the end the reciprocating mass was being retarded.

In engines of this class designed by P. W. Willans, which are now displaced by turbines, the cushioning was provided by means

of a supplementary piston that compressed air during the outstroke. The energy spent by the reciprocating masses in losing their motion during the second half of the outstroke was stored in this air and was restored in the succeeding downstroke. The engine was entirely enclosed in a casing, the bottom of which formed an oil bath where the cranks splashed to ensure ample lubrication. This feature is retained in many modern high-speed engines.

**8. Pumping Engines.**—In engines for pumping or for blowing air it is not essential to drive a revolving shaft, and in many forms the reciprocating motion of the steam piston is applied directly to produce the reciprocating motion of the pump piston or plunger. Often an inverted vertical triple-expansion engine is used, resembling the usual marine form, with a pump plunger under each of the three cylinders. Most of the power is directly transmitted from the piston to the pump, but for each cylinder there is an auxiliary crank to drive a shaft with a flywheel to equalize the effort on the pump.

A familiar example of a direct-acting pump is the small donkey pump used for feeding boilers, in which the steam piston and pump plunger are on the same rod. In some of these pumps a rotative element is introduced, partly to secure steadiness of running and partly for convenience in working the valves. But many pumps of this class are entirely nonrotative, and in such cases the steam is generally admitted throughout the stroke without expansion. The valve may be actuated by tappets from the piston rod. In some cases a tappet worked by the piston as it reaches each end of its stroke throws open an auxiliary steam valve, which admits steam to one or the other side of an auxiliary piston carrying the main slide valve.

**9. Pulsometer.**—Hall's pulsometer, a peculiar pumping engine without cylinder or piston, may be regarded as the modern representative of the engine of Savery. The sectional view, fig. 11,

FIG. 11.—HALL'S PULSOMETER

shows its principal parts. There are two chambers, A and A', narrowing toward the top, where the steam pipe B enters. A ball valve C allows steam to pass into one of the chambers and closes the other. Steam entering the right-hand chamber forces water out of it past the clack valve V into a delivery passage D, which is connected with an air vessel. When the water level in A sinks so far that steam begins to blow through the delivery passage, the water and steam are disturbed and so are brought into intimate contact; the steam in A condenses; and a partial vacuum is formed. This causes the ball valve C to rock over and close the top of A, while water rises from the suction pipe E to fill that chamber. At the same time steam begins to enter the other chamber A', discharging water from it, and the same series of

actions is repeated in each chamber alternately. While the water is being driven out there is comparatively little condensation of steam, partly because the shape of the vessel does not promote the formation of eddies and partly because there is a cushion of air between the steam and the water. Near the top of each chamber is a small air valve opening inward, which allows a little air to enter each time a vacuum is formed. When any steam is condensed, the air mixed with it remains on the cold surface and forms a nonconducting layer. The pulsometer is far from efficient as a thermodynamic engine, but its adaptability to situations where other steam pumps cannot easily be applied and the simplicity of its working parts sometimes make it useful.

**10. Marine Engines.**—The early steamers were fitted with pad-

dle wheels, and the engines used to drive them were for the most part modified beam engines. Bell's "Comet" was driven by a species of inverted beam engine, and another form of inverted beam, known as the side-lever engine, was long a favourite with marine engineers. An old form of direct-acting paddle engine was the steeple engine, in which the cylinder was set vertically below the crank. Two piston rods projected through the top of the cylinder, one on each side of the shaft and of the crank. They were united by a crosshead sliding in vertical guides, and from this a return-connecting rod led to the crank. Most modern paddle-wheel engines are direct-acting engines of the ordinary connecting-rod type, with the cylinders fixed on an inclined bed and the guides sloping up toward the shaft.

When the screw propeller began to replace the paddle wheel in ocean steamers, the increased speed required was at first obtained by using spur-wheel gearing in conjunction with one of the forms of engines then usual in paddle steamers. Types of engines better suited to the screw were introduced later and were driven fast enough to be connected directly to the screw shaft. After passing through various forms, now obsolete, the marine engine settled into one that is now universal in all screw steamships that are not driven by steam turbine. This is the inverted vertical direct-acting engine, with two or more cylinders placed side by side directly over the shaft. It has the great advantage that the shaft can readily be put at the low level necessary for screw propulsion. Two, three, and four cranks are employed, the arrangement with four cranks being especially suitable when a balance of the engine at high speeds is needed. In vessels of high speed and power the engines are often arranged in twin sets, on two shafts with twin screw propellers.

The marine engine is always furnished with a surface condenser, consisting of a multitude of brass tubes about  $\frac{1}{2}$  in. in diameter that are cooled by sea water circulated through the condenser by means of a pump. This pump and the air pump are often driven independently of the main engine.

It is in marine practice that the most powerful reciprocating engines are still to be found, although in the largest and fastest vessels the turbine has taken their place. Another and more recent rival is the internal-combustion engine, using the diesel cycle of action. The reciprocating engine continues, however, to be much used for seagoing vessels, especially those of the tramp class, most commonly in the triple-expansion form.

Often the third stage of the expansion is performed in two cylinders, making four in all. This avoids the use of a very large cylinder and secures an advantage in the better balance that can be obtained with four cranks.

**11. Locomotive Engines.**—The ordinary steam locomotive consists of a pair of direct-acting horizontal or nearly horizontal engines fixed in a rigid frame under the front end of the boiler and coupled to the same shaft by cranks at right angles, each with a single slide valve worked by a link motion or by a form of radial gear. The engine is noncondensing, except in a few special cases, and the exhaust steam, delivered at the base of the funnel through a blast pipe, serves to produce a draft of air through the furnace. In some instances a portion of the exhaust steam, amounting to about one-fifth of the whole, is diverted to heat the feed water.

On the shaft are a pair of driving wheels whose frictional adhesion to the rails furnishes the necessary tractive force. Nearly always a greater tractive force is secured by having two or more driving wheels on each side that are connected by a coupling rod between pins on the outside of the wheels.

Generally under the front of the engine there is a group of smaller wheels that do not form part of the driving system. These are carried in a bogie, that is, a small truck upon which the front end of the boiler rests by a swivel pin or plate. This allows the bogie to turn, so as to adapt itself to curves in the line, and thus obviate the grinding of tires and danger of derailment that would be caused by using a long rigid wheelbase.

In inside-cylinder engines the cylinders are placed side by side within the frame of the engine, and their connecting rods work on cranks in the driving shaft. In outside-cylinder engines the cylinders are spread apart far enough to lie outside the frame of

the engine, and they work on crankpins on the outside of the driving wheels. Many modern locomotives combine the outside and inside arrangement in order to get greater power, placing one or in some cases two cylinders within the frame, as well as two outside. The principle of compounding has often been applied to locomotive engines, but without much advantage. See RAILWAY Locomotives.

(J. A. E.; R. D. A. Br.)

### III. STEAM GENERATORS

With improvement of the steam engine there came a demand for higher pressure steam and for generators of increased capacity and efficiency. This stimulated the development of early versions of fire-tube and water-tube type boilers, forerunners of our present-day units.

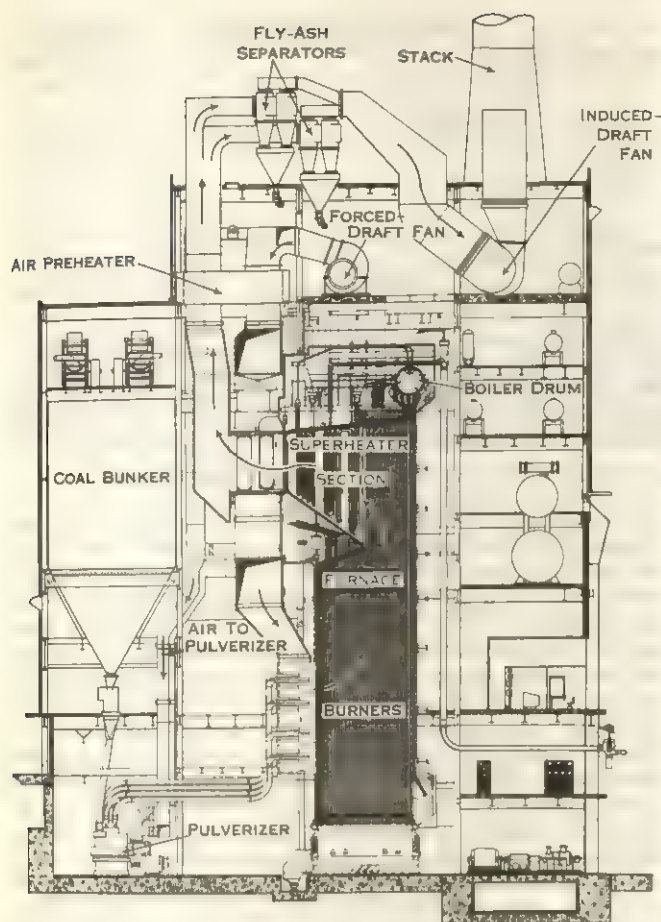

**1. Fire-Tube Boiler.**—This type boiler is characterized by the use of tubes through which hot gases flow on their way to a stack or chimney. The tubes pass through a vessel, usually cylindrical in shape, and are surrounded by the water to be converted into steam. The most popular boiler of this type is the horizontal-return-tubular boiler. In early units the fuel, usually coal, was shoveled onto the grate by hand. Air for combustion was drawn in from underneath the grate by natural draft created by the stack. The hot products of combustion first passed underneath the horizontal boiler drum to the far end, where they entered the fire tubes for their return journey to the stack. The boiler drum was cylindrical in shape and arranged so that the steam generated could collect above the water level and be withdrawn through a dry pipe consisting of a tube with perforations near the top arranged so that leaving steam was forced to make a sharp turn in order to throw out entrained moisture. A safety valve, set to allow escape of steam at pressures somewhat above normal operating pressure, was also provided. This valve is an absolute necessity on all boilers since continued addition of heat to water in a closed vessel without means of escape will result in a rise in pressure and ultimate explosion of the boiler.

Fire-tube boilers of many varieties are still being built. However, because of limitations on the pressure which a drum of reasonable size can withstand and also because of the limited heating surface available, fire-tube boilers are employed only for pressures below about 250 lb. per square inch gauge (psig) and for steam capacities not exceeding about 25,000 lb. per hour. Modern installations are often of the package type, consisting of fully automatic shop-assembled units complete with boiler drum, furnace, forced-draft fan for supplying air for combustion, and all other necessary equipment for attendant-free operation. Designed to burn either oil or gas, they have the advantage of being easy to install and operate, less costly to manufacture, and more economical to operate. They are widely used for supplying steam to large apartment buildings, hotels, small factories, and other space-heating tasks.

**2. Water-Tube Boiler.**—The development of the steam turbo-generator early in the 20th century created a demand for large quantities of steam at pressures and temperatures far exceeding those possible with fire-tube boilers. This demand resulted in the evolution of modern water-tube boilers in which steam is generated inside water tubes from heat supplied on the outside by hot furnace gases. Boilers of this type are employed in a wide variety of sizes and designs and in capacities as high as 8,000,000 lb. of steam per hour and with pressures and temperatures as high as 5,000 psi and 1,200° F (648.8° C), respectively. The largest of these units are found in central-station power plants of public utilities. Other units of substantial size are employed in steel mills, paper mills, oil refineries, and large chemical and industrial manufacturing plants.

A typical central-station water-tube boiler employing pulverized coal fuel is illustrated in fig. 12. In this unit fuel stored in the bunker is fed into pulverizers, where it is reduced to dust size and blown into the burners with air supplied from a forced-draft fan located above the furnace. Additional preheated air is supplied around the burners. Combustion takes place in the huge rectangular furnace, which is completely surrounded by water tubes in which steam is generated. The hot gases pass up the

BY COURTESY OF THE BARCOCK AND WILCOX CO.

FIG. 12.—CROSS SECTION OF A TYPICAL CENTRAL-STATION BOILER

furnace and then over the superheater tubes. From this point they move up through the air preheater, in which a part of their heat is transferred to the air on its way to the burners. Leaving the air preheater the hot gases are drawn upward through fly-ash separators into the induced-draft fan and out the stack.

Circulation of water is natural. Water from the drum near the top of the unit is carried down to the lower level of the furnace in huge pipes called downcomers. Here the water is fed into the water-wall tubes surrounding the furnace cavity. Steam is generated in these tubes and is finally returned to the drum, where it is separated from the water by means of complex devices consisting of an array of steam separators, baffles, and scrubbers. The dry steam is then passed through superheater tubes before being piped to the turbogenerators for the production of electric power.

Beginning in the early 1950s pressures above the critical (see *Properties*, above) have been employed in some central-station power plants. In these installations natural circulation is no longer feasible, since at pressures above the critical, water does not boil. As a result there is insufficient difference in density between hot and cold water to effect natural circulation, and pumps must be used.

**3. Fuels.**—Principal fuels employed for the generation of steam are coal, oil, natural gas, coke oven gas, blast furnace gas, and wood. By far the major portion of coal used for this purpose is bituminous coal, although some lignite and anthracite also are burned where plentiful. Most central-station plants burn coal in pulverized form, but many smaller industrial and heating plants burn it in lump or crushed form on traveling grate, spreader, or other type stokers.

Oil and gas are burned in central-station power plants whenever or wherever they can be purchased more economically than coal. Many plants are equipped to burn pulverized coal in the winter and natural gas in the summer. Some are equipped with burners

capable of operating with either oil, pulverized coal, or gas.

**4. Water Treatment.**—Water employed in modern steam generators must be completely free of all scale-forming or corrosive chemicals. It must also be free of dissolved oxygen and carbon dioxide. For this reason elaborate chemical treatment plants are necessary. In central-station power plants the water generated into steam is used over and over again so that only about 1 or 2% new treated water need be supplied to make up for losses resulting from leakage, contamination, blowdown, and other diversions.

The percentage of treated water added is called the makeup. In some industrial plants, such as oil refineries, nearly all steam generated is from makeup. This means that virtually 100% of the water going into the boiler must be treated.

**5. Efficiency.**—The generation of steam involves the transfer of heat from the fuel to the boiler fluid. In this process some of the heat released by the fuel is lost and is therefore not absorbed by the steam. The ratio of the heat actually absorbed by the steam to the heating value of the fuel employed is called the efficiency of the steam generator.

Because of high fuel costs, efforts to reduce heat losses to a minimum include the use of an economizer to preheat the feed water entering the boiler and an air preheater to preheat the air before being introduced into the furnace for combustion. Both of these items aid in cooling the hot flue gases to a lower temperature so that not so much heat is discharged from the stack. Other precautions involve the use of the exact amount of air for efficient combustion. This operation involves the supply of sufficient excess air to assure complete combustion of all carbon to carbon dioxide, yet not so much that excess heat is thrown away by heating unnecessary air. This air supply is governed by intricate controls that automatically maintain the correct air-to-fuel ratio for maximum overall steam-generator efficiency. In modern central-station plants, steam generators are capable of achieving efficiencies as high as 90% based on the higher heating value of the fuel, and average efficiencies of about 87% are common. For small steam generators not employing elaborate control apparatus, economizers, or air preheaters, efficiencies of the order of 70 to 80% are typical. See also **BOILER**.

#### IV. STEAM POWER PLANTS

A steam power plant is a plant for the generation of electric power with steam. By far the major portion of electric power generated in the world comes from central-station power plants. In the United States in the mid-1960s total power generation amounted to slightly more than 1,000,000,000,000 kw-hr., of which about 91% was generated in electric utility plants. Of this total, 82% was generated in fuel-burning plants and 18% in hydroelectric plants. A breakdown of the types of fuel employed indicated that 66% of the power generated in fuel-burning plants was generated from coal, 27% from gas, and most of the remainder from oil and nuclear energy. Similar statistics, but on a smaller scale, would be true of other countries. All serve to emphasize the importance of steam power plants in our modern economy.

**1. Modern Power Plants.**—Fig. 13 illustrates a typical central-station power plant and the various items of equipment employed in the generation of electrical power from coal. Coal cars dump their contents into a hopper and then onto a coal conveyor. From there the coal is lifted onto a belt conveyor and deposited in huge coal bunkers from which it is automatically fed to the coal pulverizing mills as needed. From the pulverizing mills the coal is blown into the boiler furnace where it is burned with preheated air supplied by the forced-draft fan. The hot combustion gases formed pass over the various boiler heating surfaces, through the economizer, air preheater, precipitator, induced-draft fan, and finally to the stack.

In the particular plant shown the saturated liquid water from the condenser enters the condensate pumps and is pumped through the first heater into the deaerating heater, where any entrained air is expelled. From the deaerating heater it flows to the boiler feed pumps, which force it successively through three other feed-water heaters and then through the economizer into the boiler.

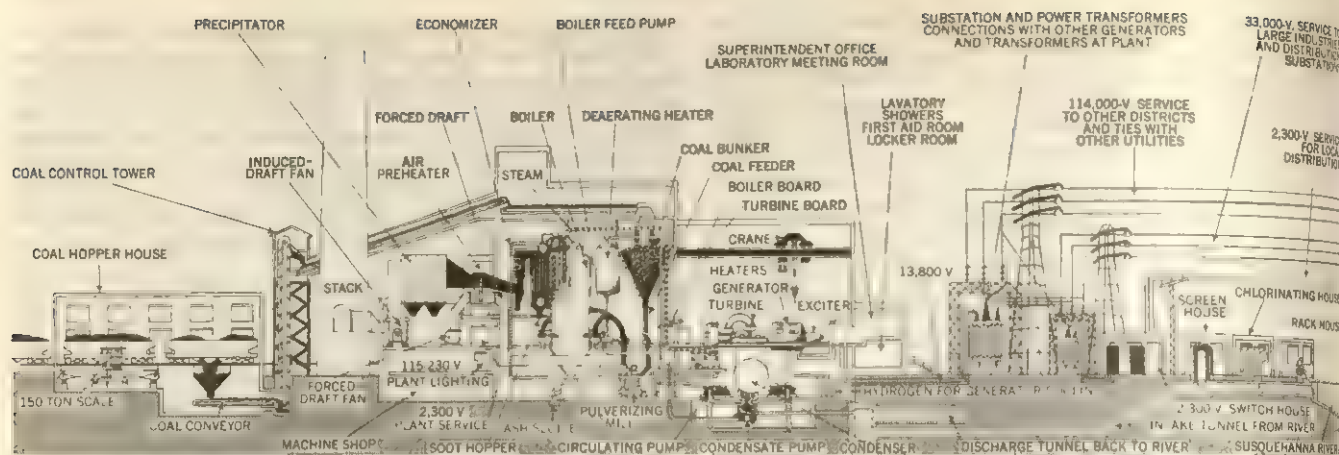

FIG. 13.—TYPICAL CENTRAL-STATION POWER PLANT, THE WESTOVER STATION OF THE NEW YORK STATE ELECTRIC AND GAS CORP.

Here it is generated into steam and after passing through the superheater flows into the turbine, where the power is generated. From the turbine the steam exhausts to the condenser, where it is divested of its latent heat by means of the circulating water pumped from a nearby river through the tubes of the condenser. The electric generator furnishes 60-cycle current at 13,000 v. In the substation, transformers are used to step the voltage up or down for transmission from the plant.

Modern steam power plants all employ regenerative cycles and many employ reheat. However, pressure and temperature conditions, number of heaters, and details of arrangement vary greatly. During the 1950s and 1960s the trend was toward higher pressures and temperatures, with a few supercritical units of huge capacity being built. One unit employed steam at 5,000 psig and 1,200° F (648.8° C), with two reheats, the first to 1,045° F (562.7° C)

and the second to 1,050° F (565.6° C); it generated 325,000 kw. A number of other units operated with steam pressures of 3,500 to 4,500 psig and steam temperatures of around 1,000° F (537.8° C) with one reheat to 1,000° F. The capacity of these units varied, but most were 450,000 kw. and larger. A flow diagram for a supercritical unit of 450,000-kw. capacity is shown in fig. 14.

The efficiency of coal-burning and other steam power plants has increased remarkably since the turn of the century. In 1900 the best plants were capable of achieving only about one-third of a kilowatt hour of electrical energy per pound of coal, while average plants achieved only one-fifth or less. In the mid-1960s, the best plants were capable of generating about 1.33 kw-hr. per pound of coal, an increase of about four to one in 60 years. Average plants generated roughly 1.16 kw-hr. per pound of coal.

The cost of central-station power plants varies widely, but in

the mid-1960s an average figure was about \$150 per kilowatt of generating capacity. This means a typical modern central-station plant capable of generating 600,000 kw. would involve an investment of about \$90,000,000 for the plant. To this must be added the cost of transmission, distribution, and miscellaneous capital equipment costs. From 1955 to 1965 the annual construction expenditures of U.S. electric power companies for plant, transmission, distribution, and miscellaneous equipment averaged about \$3,500,000,000.

## 2. Nuclear Power Plants—

Following World War II the use of nuclear energy for the generation of power became feasible. A number of plants were built in the U.S., England, the U.S.S.R., and other countries. In these plants steam is still the motivating force and is generated with the aid of a reactor in which the controlled fission of uranium or plutonium furnishes the necessary heat for its vaporization. Thus the reactor takes the place of the steam generator of the conventional plant.

Problems associated with nuclear power generation are extremely complex and involve such considerations as shielding against radiation, disposal of fuel

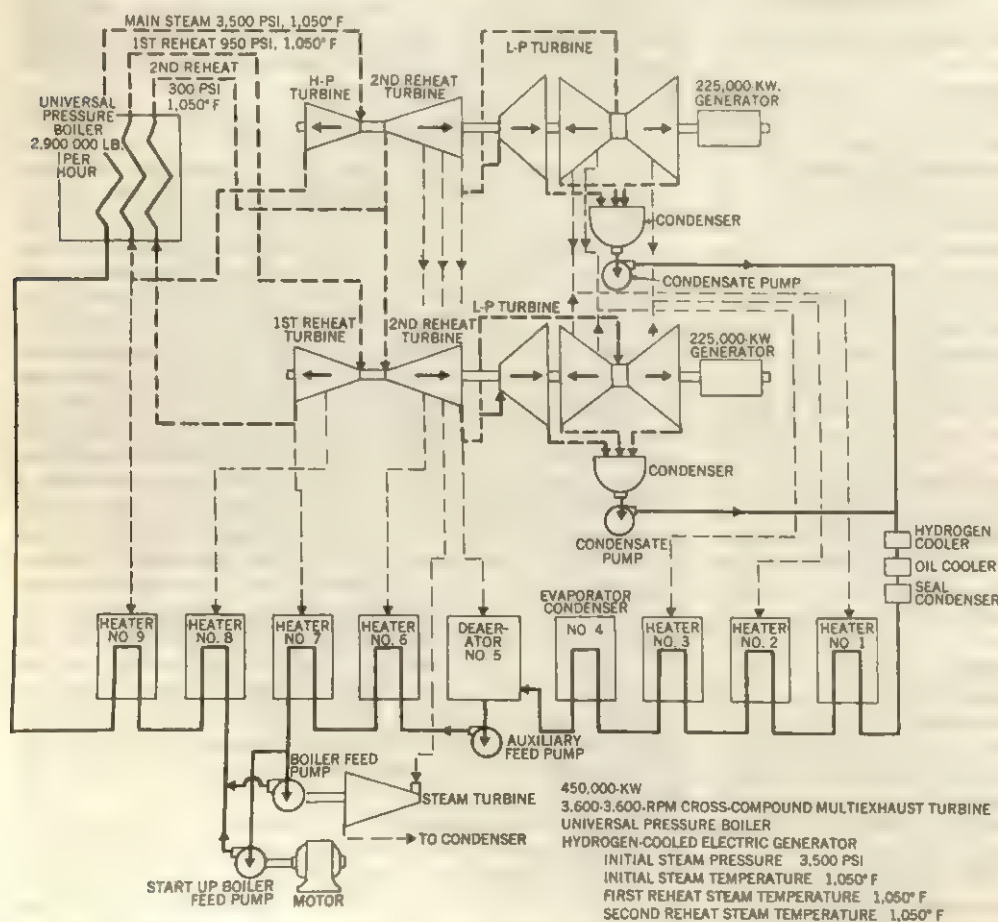

FIG. 14.—FLOW DIAGRAM OF 450,000-KW. SUPERCRITICAL POWER PLANT

sion products, hazard insurance, and high cost of construction. Because of these factors, early plants built in the U.S. were not economically competitive with coal-burning plants. However, with improved technology, plants of large size became competitive in certain locations in the U.S. in the mid-1960s. In 1964 about one-tenth of one per cent of the power generated in the U.S. was with nuclear fuel. As more experience is gained the use of nuclear fuel is expected to increase rapidly.

**3. Binary Cycle Plants.**—To achieve maximum efficiency, heat should be added to the cycle at the highest possible temperature. In conventional steam power plants a substantial portion of the heat is added at temperatures below the critical of  $705.4^\circ\text{F}$  ( $374.11^\circ\text{C}$ ). This is because the feed water supplied to the boiler must first be heated to the boiling point and then evaporated at the saturation temperature corresponding to the pressure. In the binary cycle plant this limitation is overcome by simultaneously employing two separate cycles, one a high-temperature Rankine cycle using mercury vapour, and the other a conventional steam cycle. The arrangement of the two cycles is such that most of the heat from the fuel is added at high temperatures to the mercury in a special boiler that need not withstand very high pressure. The mercury vapour is expanded through a mercury turbine and exhausted into a special condenser (called a condenser-boiler) that also serves as the boiler for the steam cycle. The condensing mercury thus supplies the latent heat of vaporization of the steam before it is pumped back into the mercury boiler. The steam generated is superheated in the furnace of the mercury boiler and then subjected to the conventional regenerative cycle, after which it is returned to the condenser-boiler for reuse. Although high efficiencies were obtained by this cycle, difficult design and heat-transfer problems limited its development. During the 1930s several large plants were constructed, but for economic reasons the binary cycle was abandoned in favour of high-pressure steam cycles employing multiple reheat.

**4. Combination Steam- and Gas-Turbine Cycles.**—Another means of increasing the efficiency and capacity of steam power plants is the use of a combination gas-turbine and steam-turbine cycle. There are a number of possible combinations but in general the objective is to direct the hot exhaust gases from a gas turbine, while they still contain approximately 15% oxygen, through the furnace of the steam generator, thus reducing the amount of pre-heated air required for combustion of the fuel. An increase of about 5% in thermal efficiency is realized by this means. By the early 1960s a number of units of this type had been built, but more were expected to be installed as improvements were made.

**5. Industrial Steam Power Plants.**—There are a wide variety of industrial plants that generate their own electrical energy. Usually such plants require a great deal of steam, and it is economical to generate this at higher pressure and temperature in order to permit passage through a noncondensing turbine before otherwise making use of it. In this manner by-product power may be obtained at low cost. Automatic extraction turbines are available for this purpose. With these, variable quantities of steam can be extracted at one or more desired fixed pressures, regardless of the electrical load carried. In industrial plants exhaust steam is also often used for space-heating purposes.

**6. Theory.**—As may be inferred from fig. 15, the generation of power from steam is accomplished by a cycle of events involving the addition of heat in a boiler and the rejection of heat in a condenser. For the sake of simplicity in developing the theory one may start with the simple Rankine cycle, named after the gifted Scottish engineer and scientist W. J. M. Rankine (*q.v.*; 1820–72) of Glasgow University. Fig. 15 illustrates the essential components of the Rankine cycle, together with an idealized diagram of the various processes involved as they would appear on a Mollier chart.

Starting at the outlet of the condenser the water enters the boiler feed pump in the saturated liquid state with enthalpy  $h_{f2}$  and is pumped into the boiler at the enthalpy represented by  $h_3$ . In the boiler sufficient heat is added to vaporize the water into steam and superheat it to the enthalpy represented by  $h_1$  on the chart. From here the steam flows into the turbine, through which

FIG. 15.—DIAGRAM AND MOLLIER CHART FOR AN IDEAL RANKINE CYCLE STEAM POWER PLANT

it expands to the enthalpy  $h_2$  turning the rotor and electric generator. The steam then flows into the condenser, where it is converted into saturated liquid with an enthalpy  $h_{f2}$ . This is accomplished by transferring the latent heat of the steam to large quantities of circulating water flowing through the tubes of the condenser. From the condenser the water again enters the boiler feed pump to be returned to the boiler for generation into steam.

The thermal efficiency of any power plant cycle is equal to the net work performed divided by the thermal energy expended to perform that work. Since all energy must be accounted for, and also since energy is added only in the boiler,

$$\text{Thermal efficiency} = \eta_T = \frac{\text{net work performed}}{\text{heat added}} = \frac{\text{heat added} - \text{heat rejected}}{\text{heat added}} \quad (7)$$

Using the fact that heat added and heat rejected during steady-flow processes is equal to the change in enthalpy, one may write for the ideal Rankine cycle

$$\eta_{TR} = \frac{W_{\text{cycle}}}{Q_A} = \frac{W_t - W_p}{Q_A} = \frac{Q_A - Q_R}{Q_A} = \frac{(h_1 - h_2) - W_p}{(h_1 - h_{f2}) - W_p} \quad (8)$$

where for the cycle shown:

- $\eta_{TR}$  = thermal efficiency of ideal Rankine cycle
- $W_{\text{cycle}}$  = net work performed by the cycle, BTU per pound of steam
- $W_t$  = work performed by the turbine, BTU per pound of steam
- $W_p$  = work performed on the boiler feed water pump, BTU per pound of steam
- $Q_A$  = heat added in the steam generator, BTU per pound of steam
- $Q_R$  = heat rejected in the condenser, BTU per pound of steam
- $h_n$  = enthalpy of the steam or water at the various sections indicated by subscripts, BTU per pound

Examination of equation (8) shows that the efficiency of the cycle can be increased by increasing the amount of heat added  $Q_A$  relative to that rejected  $Q_R$ . One method of increasing the heat

added is to raise the pressure and temperature of the steam supplied to the turbine. This explains the trend toward increasingly high temperatures and pressures. Another method of increasing the efficiency is to avoid having to throw away so much heat to the condenser in comparison to that added in the boiler. This may be accomplished by withdrawing steam from the turbine at various stages of expansion and using this steam to heat the feed water being returned to the boiler. This process, called regeneration, is accomplished with the aid of feed-water heaters as indicated in fig. 16A, which is drawn to represent a typical regenerative reheat cycle. Examination of the cycle reveals that all steam bled from the turbine for the purpose of heating the feed water goes through a Rankine cycle similar to that in fig. 16A, but that the latent heat of this bled steam is not thrown away in the condenser. Instead it is absorbed by the condensate on its way back to the boiler. This means that more than one pound of steam is generated in the boiler per pound of steam condensed in the condenser, and that, therefore, more heat is added compared to that rejected.

In modern central-station power plants about 30% of the steam entering the turbine is withdrawn for feed-water heating. The result is a 10 to 15% increase in thermal efficiency.

In fig. 16, the expansion through the turbine is shown in much the same way as it would actually occur. Because of losses in the turbine, the expansion takes place along the solid lines to the right of the ideal isentropic (constant entropy) lines shown dotted.

FIG. 16.—DIAGRAM AND MOLLIER CHART FOR A REHEAT-REGENERATIVE POWER PLANT CYCLE

Also one reheat is shown in which steam, after passing partway through the turbine, is returned to the boiler to be reheated before continuing its expansion through the remaining stages of the turbine.

From the diagram in fig. 16, and from the principle that work of expansion is equal to the weight of steam flowing times its change in enthalpy, the work performed by the steam in British thermal units per hour can be computed as follows:

$$W_{\text{steam}} = w_1(h_1 - h'_{a1}) + (w_1 - w_a)(h_{a2} - h_a) + (w_1 - w_a - w_b)(h_b - h_b) + (w_1 - w_a - w_b - w_c)(h_c - h_c) + (w_1 - w_a - w_b - w_c - w_d)(h_d - h'_2) \quad (9)$$

where

- $w_1$  = flow of steam to turbine, pounds per hour
- $w_a$  = flow of steam from the various bleedpoints indicated by subscript  $a, b, c$ , and  $d$ , pounds per hour
- $h_1$  = enthalpy of steam entering turbine, BTU per pound
- $h'_{a1}$  = enthalpy of steam returned for reheat, BTU per pound
- $h_{a2}$  = enthalpy of steam after reheat, BTU per pound
- $h_a$  = enthalpy of steam flowing from the various bleedpoints indicated by subscript  $a, b, c$ , and  $d$ , BTU per pound
- $h'_2$  = enthalpy of steam leaving turbine, BTU per pound

The net work of the power plant is obtained by subtracting the exhaust loss, mechanical loss, generator loss, and auxiliary power requirements of the plant, including pump work, from  $W_{\text{steam}}$  (see TURBINE).

The heat added by the fuel is obtained by multiplying the steam flow through the boiler by its increase in enthalpy in the boiler, superheater, and reheater and dividing by the boiler efficiency. Thus,

$$Q = \frac{w_1(h_1 - h_f) + (w_1 - w_a)(h_{a2} - h'_{a1})}{\eta_{sg}} \quad (10)$$

where:

- $h_f$  = enthalpy of boiler feed water entering the steam generator BTU per pound
- $\eta_{sg}$  = efficiency of steam generator, BTU per pound

The thermal efficiency of the regenerative-reheat power plant is therefore

$$\eta_{TP} = \frac{W_{\text{plant}}}{Q_A} = \frac{(W_{\text{steam}} - W_{\text{ex}} - W_M - W_G - W_{\text{aux}})\eta_{sg}}{w_1(h_1 - h_f) + (w_1 - w_a)(h_{a2} - h'_{a1})} \quad (11)$$

where

- $W_{\text{ex}}$  = exhaust loss, BTU per hour
- $W_M$  = mechanical loss, BTU per hour
- $W_G$  = generator loss, BTU per hour
- $W_{\text{aux}}$  = auxiliary power including pump work, BTU per hour
- $h_n$  = enthalpy at various points indicated by subscripts, BTU per pound
- $\eta_{sg}$  = steam generator efficiency

Thermal efficiency of modern central-station power plants varies widely depending on steam conditions, number of feed-water heaters, and complexity. The range is from about 30% in the poorest stations to about 40% in the very best.

**STEARIC ACID** is one of the more important long-chain fatty acids (see CARBOXYLIC ACIDS) that occur in fats isolated from plants and animals. It is a predominant component of body fats; lard and tallow, for example, often contain up to 30% of stearic acid. Like other fatty acids, it does not occur in the free state but is normally found as an ester of glycerol (*i.e.*, as a glyceride) or as an ester of a long-chain alcohol. Tristearin is a typical example of a triglyceride; it is a triester of glycerol and stearic acid.

Stearic acid,  $\text{CH}_3(\text{CH}_2)_{16}\text{CO}_2\text{H}$ , is a colourless solid that exists in various crystalline forms of which that melting at  $69.6^\circ\text{C}$  is the most stable. It is a monocarboxylic acid and shows all the reactions typical of this class of organic compounds. Of chief importance are its metal salts and its esters.

Soaps are the sodium or potassium salts of long-chain carboxylic acids and are prepared by the alkaline hydrolysis of the glyceride components of natural fats. This process is often described as saponification. For the manufacture of soaps and edible fats, solid fats are preferable to liquids, and, since the compounds with lower melting points are unsaturated, hydrogenation of oils yields solid fats. This process is called hardening and is illustrated by the hydrogenation of the oil triolein (the triglyceride of oleic acid) to solid tristearin (melting point  $71^\circ\text{C}$ ). See also OILS, FATS AND WAXES.

**STEEL:** see ALLOYS; ARCHITECTURAL ENGINEERING; CONVERTER STEEL; HIGH-SPEED STEEL; IRON AND STEEL INDUSTRY; MANGANESE STEEL; MOLYBDENUM; NICKEL-CHROMIUM STEELS; NICKEL STEEL; NITRIDING; STAINLESS STEEL; STEELS, ALLOY; TOOL STEEL; WIRE; and other specific headings.

**STEEL CONSTRUCTION.** Steel fabrication of buildings and bridges has been a natural consequence of progress in the production of steel itself and of improved steel alloys. Even before the development of the Bessemer and open-hearth steel-making processes in the latter half of the 19th century, which resulted in a rapidly expanding supply of cheap steel, cast and wrought iron had been used to a limited extent in bridge and building construction. As early as 1800 a technique had been developed for passing iron, heated to a plastic state, between rolls to form structural shapes. These shapes were small, however, and of a profile that limited their structural usefulness. It was not until the 1850s that rolled beams of wrought iron were used in floor construction, in the Cooper Union in New York City. Unlike the familiar I-beams of modern manufacture, these beams resembled in profile an inverted modern railroad rail. By the time structural steel became commercially available in the early 1880s, the basic structural shapes—I-beams, channels, and angles—had proved their adaptability to the builder's needs. When combined with plates of various widths and thicknesses, they could be fabricated into efficient members of any required size and strength, and these members could be joined together in the field, using hot-driven rivets.

**Steel-Framed Buildings.**—In 1889 the Eiffel Tower, designed as a latticed girder with a complete system of vertical diagonal bracing, was erected in Paris to a height of 984 ft. (1,056 ft. high from the base of the structure, including a 55-ft. television mast added later). Since it was an open steel-framework construction, the total wind pressure against it was much less than it would have been against the sides of an enclosed building of the same height. This tower was to remain the highest man-made structure for more than 40 years. During that time other systems of bracing for tall enclosed buildings were evolved, depending in part upon the use of diagonal bracing, which in effect formed upended cantilever trusses, and in part upon the bending stiffness of all the beams and columns, joined to one another by means of very rigid connections.

Use of the skeleton frame, with exterior curtain walls supported at each floor, released building construction from any height limi-

tation due to the excessive thickness of masonry-bearing type walls. The most spectacular examples of this type of construction have been so-called skyscrapers, originally built to effectively utilize expensive urban real estate. (See ARCHITECTURE.) The Home Insurance Building, erected in Chicago in 1885 and torn down in 1931, has been generally acclaimed the forerunner of the modern skyscraper. It was the first multistoried building having masonry walls supported on a complete structural frame. The columns of the Home Insurance Building were cast iron. The first five floors were framed with wrought-iron beams, but the next five were framed in steel, which had only just become available and offered an attractive cost saving. In 1889 two more floors, framed in steel, were added. By mid-20th century hundreds of skeleton steel frame buildings higher than the Home Insurance Building had been erected in the United States.

The 102-story Empire State Building, which was completed in 1931 in New York City, exceeded the height of the Eiffel Tower by 266 ft. A 222-ft. television antenna mast, added in 1950, increased this height to 1,472 ft. This record height was exceeded in 1954, however, with the erection of a television antenna tower near Oklahoma City, Okla. Guyed with wire rope to provide lateral support, this structure rose 1,572 ft. above its ground-level foundations.

A number of interesting examples of steel dome construction can be cited. As early as 1894, for example, an exhibition building of spectacular clear span was constructed at Lyons, France. Its central portion consisted of a dome springing from a 361-ft.-diameter circle at ground level to an apex 180 ft. above ground. Encircling this large unobstructed area was a 131-ft. bay, having a roof that sloped down and away from the central dome. Another structure, the Dome of Discovery, constructed for the Festival of Britain in London (1951), utilized a steel tension ring 342 ft. in diameter, resting 48 ft. above the ground on steel supports battered outward slightly to form a 365-ft.-diameter circle at ground level. Both these structures were subsequently razed.

During the period from 1894 to 1951 the possibilities of steel dome construction, for enclosing large unencumbered areas suitable for assembly purposes, received scant attention. Since that time, however, a number of such structures have been erected. The record-breaking steel-framed roof enclosing the Harris County (Texas) Stadium, called the Astrodome (1965), provides a clear diameter of 642 ft. at its bottom tension ring. Covering over nine acres, it encloses a full-size playing field and seating area, with provision for air conditioning. The 400-ft. dome-shape roof over the Pittsburgh, Pa., Public Auditorium (1961) consists of six power-operated, retractable sections and two stationary sections, pie-shape in plan. The movable leaves are pivoted at the crown to an exterior supporting frame cantilevered out over the stationary portion of the roof. The bottom edge of these leaves is supported on wheels that travel on circumferential tracks. The sections are so constructed as to nest one inside of the next. The structural framework is covered by a stainless-steel sheath.

The aviation industry had been responsible for the construction of a number of very large buildings having wide areas free of supporting columns. Notable among these were the aircraft assembly building at Bristol, Eng., and the maintenance hangar at Kelly Air Force Base, San Antonio, Tex. The former, completed in 1948, provided three adjoining clear aisles 331 ft. wide and a clear height of 65 ft., serviced by overhead cranes of 12 tons' lifting capacity. Latticed box frames provided the necessary support for the roof and cranes. The maintenance hangar at Kelly Field covered a total area of approximately 23 ac., more than half of this in a single  $300 \times 2,000$ -ft. bay.

The Vehicle Assembly Building, erected for assembling space rockets at Cape Kennedy, Fla., is essentially a one-story structure 526 ft. high. Two 250-ton bridge cranes, spanning 150 ft. and located just under the roof, provide the means for lifting components from the ground floor and assembling them on a movable platform provided for transferring the completed rocket to its launching site.

**Steel Bridges.**—The first all-steel bridge, crossing the Missouri River at Glasgow, Mo., was erected in 1879, a century after the

Construction of the Vehicle Assembly Building on Merritt Island, near Cape Kennedy, Fla.: (left) 16-in.-diameter pilings being driven 150-170 ft. into bedrock; (above) the half-completed superstructure of steel girders; (below) aluminum and plastic panels being attached to the steel skeleton at its full height (526 ft.); (right) virtually completed building, the largest, by volume (129,000,000 cu.ft.), in the world

first iron bridge had been constructed at Coalbrookdale, Eng. Since that time steel has been used in thousands of bridges, employing various structural systems (e.g., suspension cables, cantilevers, and arches) to span great distances without intermediate support. The longest single span (4,260 ft.), that of the Verazano-Narrows Bridge astride New York Harbor, which opened to traffic in 1964, exceeds by 60 ft. the main span of the Golden Gate Bridge (1937) in San Francisco, Calif. At least seven other suspension bridges have spans longer than any supported by other structural systems.

The two record-making 1,710-ft. spans of the Firth of Forth Bridge (Scot.), completed in 1890, each consist of a 350-ft.-long centre truss supported on 675-ft. cantilever arms. This cantilever-type construction was employed 28 years later to establish a new record with the 1,800-ft. main span of the Quebec Bridge in Canada. The earlier Firth of Forth Bridge was paralleled in 1964 by a suspension bridge having a 3,300-ft. centre span.

The Kill van Kull (Bayonne) Bridge in New York City, spanning 1,652 ft. between masonry piers, established a record as the longest single steel arch. Completed in 1931, it exceeded in length by only a few feet a similar structure spanning Sydney Harbour (Austr.), opened to traffic in 1932.

A bridge completed in Belgrade, Yugos., in 1957 contained the longest single-plate girder. Continuous for three spans, the load on its 856-ft. centre portion was largely counterbalanced by the weight of the 246-ft. end spans. This unusual span for a girder-type bridge was made possible by the use of a light deck construction consisting of stiffened steel plates covered by a relatively thin bituminous pavement, in lieu of a much heavier conventional structural concrete slab. This type of bridge deck, known

as "orthotropic plate," was developed in Germany during the reconstruction period following World War II. Other outstanding examples of girder bridges include the Düsseldorf-Neuss continuous girder bridge with a 675-ft. centre span (1951), the Cologne-Mülheim suspension bridge with a 1,033-ft. centre span (1951), and the 1,200-ft. Port Mann arch bridge (1964) in Vancouver, B.C.

#### Technological Advances.

The use of welding made possible the introduction of lighter fabricated structural members. For example, open-web (lattice) steel joists were developed for use as floor beams and roof purlins in lieu of heavier rolled shapes. In Europe whole structures at mid-20th century utilized steel pipe and seamless tubing, welded together to form trusses, latticed columns and joists, and supplementary bracing. Welding was also used in the fabrication of heavier structural members and frames, frequently from flat plate. Neater connections being possible, exposed steelwork itself became a medium of architectural expression. High-strength bolts as a substitute for rivets in field connections meantime became popular in the United States.

With mass production techniques, steel floor and wall panels and roof decking came to play a major role in building construction. Cold-formed from light-gauge sheets, these products could span considerable distances with substantial saving in dead weight. Deeply corrugated for strength and stiffness, and backed up with a flat sheet, the cells of the panels thus formed were utilized as underfloor ducts for electrical wiring. Sandwichlike panels, consisting of one smooth and one ribbed or fluted sheet separated by a core of insulating material, were used extensively for the exterior walls of industrial buildings.

The facades of a number of modern office buildings consisted entirely of glass windows and stainless-steel panels bolted to the steel building frame. These panels, press-formed from light-gauge sheets to various designs and backed up with thermal insulation about four inches thick, were lighter, more durable, and less conductive of heat than older types of curtain wall construction. In one building alone the equivalent of 11 ac. of stainless-steel paneling was used in the exterior walls.

Approximately one-sixth of the world's steel production is used by the construction industry; only two-thirds of this amount, comprising those steel products required for structural purposes, comes within the category loosely referred to as steel construction. Of this amount, items fabricated from hot-rolled carbon steel structural shapes, bars, and plates (as for example, bridges, building frames, supports for industrial equipment, towers, and tanks, account for a larger tonnage of steel than all others combined.

(T. R. H.)

**STEELE, SIR RICHARD** (1672–1729), Irish essayist, dramatist, and politician, who, with Joseph Addison (*q.v.*), wrote most of *The Tatler* and *The Spectator*. He was born in Dublin, where he was baptized on March 12, 1672. His father died late in 1676, and his mother in the following year, but, under the guardianship of his uncle Henry Gascoigne, confidential secretary to the duke of Ormonde, he was sent to Charterhouse in 1684, and in 1689 to Christ Church, Oxford. At Charterhouse he met Addison, and this was the beginning of one of the most fruitful of all literary relationships, which lasted until political differences brought about an estrangement shortly before Addison's death in 1719. From Christ Church Steele went on to Merton in 1691 but left in 1692, without taking a degree, to join the army. He enlisted in the Life Guards, later transferring to the Coldstream Guards. He was commissioned in 1697 and promoted captain in 1699. In 1700 he was challenged to a duel by a fellow officer, Captain Kelly, and gravely wounded him; this incident inspired his hatred of dueling.

Steele's first major publication was a moralistic prose tract, *The Christian Hero* (1701), wherein he draws on his experiences of the "irregularity" of army life to advance the view that only the religious man is truly great. He was mocked for the contrast between his austere principles and his genially convivial practice, but he was unquestionably sincere, and this early work foreshadows much of his later writing. Aware of the jeers of his fellow officers, however, he wrote *The Funeral*, his first comedy, acted at Drury Lane in 1701 with "more than expected success." This was followed late in 1703 by *The Lying Lover*, one of the first sentimental comedies (see **DRAMA: Modern Drama: The Evolution of Middle-Class Drama**). With its sententious blank verse passages and priggish moralizing, it ran for only six nights, being, as Steele said, "damned for its piety"; but there is much of Steele in it: a protest against dueling, a regard for the qualities of "the fair sex," and a wry allusion to the gullible author's having been recently defrauded by an alchemist. Steele was, indeed, always ready to entertain moneymaking projects and later spent much time and energy on a scheme for transporting live fish in specially constructed boats.

Need for money dominated Steele's life: he found it easier to get than to keep, and actions for debt were always in the background, and often in the foreground, of his impulsively extravagant existence. His third play, *The Tender Husband* (1705), which Addison helped him to write, had some success, and in the next few years he secured various minor appointments, including that of a gentleman waiter to Prince George, and, more important, the office of gazetteer, editing a government-sponsored news-sheet at £300 a year. In 1705 he had married Margaret Stretch, a widow who owned land in Barbados; she died in 1706, leaving him what he estimated, overoptimistically, as an annual income of £850. In 1707 he married Mary Scurlow (d. 1718), the "Dear Prue" of his charming and lively correspondence. Of their four children only the eldest long survived her father.

The *Gazette* gave little opening for Steele's literary talents, and on April 12, 1709, he launched a thrice-weekly paper, *The Tatler*. This began a new chapter in the history of the periodical (*q.v.*). Steele wrote under the name "Isaac Bickerstaff," already made famous by Jonathan Swift (*q.v.*), and created the mixture of entertainment and instruction in manners and morals to be perfected in *The Spectator*. The essays were dated from different coffeehouses, so that Steele could effectively cover the interests of most of the fashionable and would-be fashionable world. Addison began to contribute with the 18th number and wrote about 46 papers in all, while some 36 were written by the two jointly; but the great bulk of the 271 issues were by Steele, and *The Tatler* enjoyed a prosperous run before it stopped, on Jan. 2, 1711. With the shift in power to the Tory Harley as chancellor of the exchequer, the Whig Steele had lost his gazetteership in October 1710 and came near to losing the post of commissioner of stamps, to which he had been appointed in the same year. During 1710 *The Tatler* had contained a good deal of political innuendo, some of it directed at Harley himself, and it may be that Harley brought pressure on Steele to discontinue the

THE BETTMANN ARCHIVE

STEELE; PORTRAIT BY JONATHAN RICHARDSON, 1712

journal; certainly Addison seems not to have been consulted.

Whatever the cause of *The Tatler's* demise, its brilliant successor, appearing on March 1, 1711, was avowedly nonpolitical. *The Spectator* was a joint venture, and though Addison's contributions were perhaps more distinguished, Steele's was probably the more original and vivacious journalistic flair. He evolved many of the most successful ideas and characters, including Sir Roger de Coverley (*q.v.*), and his attractive, intimate style formed a perfect foil for Addison's more polished, erudite craftsmanship. Of the 555 daily numbers, up to Dec. 6, 1712, Steele wrote about 240.

He made many later ventures into periodical journalism, some purely political. The most notable were *The Guardian* (March 12–Oct. 1, 1713), with considerable assistance from Addison; *The Englishman* (Oct. 6, 1713–Feb. 11, 1714; July 11–Nov. 21, 1715); *The Lover* (Feb. 25–May 27, 1714), 40 of Steele's most attractive essays; and *The Reader*, *Town Talk*, and *The Plebeian*, all short lived but sometimes of considerable political importance. Steele became, indeed, the chief journalist of the Whigs in opposition, a writer of principle and integrity.

Many of his essays and pamphlets were collected in *Political Writings* (1715). These had stirred up enough storms to make his career far from smooth. He resigned as commissioner of stamps in 1713 and was elected member of Parliament for Stockbridge on Aug. 25; but after his pamphlets *The Importance of Dunkirk Consider'd* (1713)—following several *Guardian* papers calling on the Tories to honour the clause in the Treaty of Utrecht providing for demolition of Dunkirk—and *The Crisis*, defending the Hanoverian succession (1714), he was denounced in the Commons for seditious writings and expelled. Calmer weather followed with George I's accession, and Steele obtained various posts, most notable being that of a commissioner of Drury Lane Theatre (1714); shortly after this, he published his informative and dignified *Mr. Steele's Apology for Himself and His Writings*. In 1715 he was elected for Boroughbridge and knighted. In 1722 he changed constituencies and was elected for Wendover.

Steele's health was gradually undermined by his cheerful intemperance, and he was long plagued by gout. Nevertheless, he occupied himself conscientiously with politics and, more erratically, with the management of Drury Lane. One of his main contributions to its prosperity was his last and most successful comedy, *The Conscious Lovers* (1722); considered to be his best play, it is characteristic in its combination of vivacity and sentimentality, and its insistence on the value of the generous impulse.

In 1724 Steele retired to his wife's estate at Llangunnor in Wales and began to settle his debts. He suffered a paralytic stroke in 1726, and on Sept. 1, 1729, the genial and charming writer whose burly figure, brown face, and brilliant eyes had long been part of the London scene, died at Carmarthen.

**BIBLIOGRAPHY.**—*Editions: Dramatic Works* (1894), *The Tatler*, 4 vol. (1898–99), both ed. by G. A. Aitken; *The Spectator*, ed. by D. F. Bond (1962). A definitive edition of the complete works, by R. Blanchard, includes *The Christian Hero* (1932), *The Correspondence* (1941), *Tracts and Pamphlets* (1944), *Occasional Verse* (1952), *The Englishman* (1955), and *Periodical Journalism, 1714–16* (1959).

(R. P. C. M.)

**STEELS, ALLOY.** It has been said that alloy steel is "a carefully made steel with sufficient alloying metals added to it to modify usefully the properties of a plain carbon steel." An alloying element or compound is one that is more or less soluble in the major metal and that participates in physical or chemical reactions at various temperatures and thus modifies the properties. Alloying metals may be various. The amount of alloying element added ranges from very low (0.0005% boron or 0.1% vanadium) to very high (20% chromium or more).

It is almost as hard to draw a clear line of demarcation between alloy steels and steels as it is between steel and iron. Diverse definitions have been set up legally for customs purposes, and commercially for statistical but more especially for pricing purposes.

Iron is produced from its ores by commercial processes that leave a number of impurities, either alloyed with it or included as insoluble nonmetallic particles. Carbon (in the chemical compound iron carbide, cementite,  $\text{Fe}_3\text{C}$ ) is the principal alloying element in iron, proportionately increasing its strength and hardness, especially after correct heat treatment. Only a little iron carbide is needed to convert iron into a hardenable steel, so a metallographer's definition of carbon steel might well be "a malleable alloy of iron and iron carbide" (malleable being inserted to distinguish plain carbon steel from cast iron, which is a non-malleable alloy of the same substances). Fractional percentages of the alloying metals manganese and silicon also must be present in commercial plain carbon steels, and it is difficult to say, as these incidental elements increase, just where a carbon steel stops and a manganese alloy steel (or, more briefly, a manganese steel) and a silicon steel start. Likewise alloy steel practice consists of far more than adding alloying metals to the liquid steel. The raw material is selected for a low content of deleterious impurities, the furnace practice is extended to include a careful refining period, additions are made to control the grain size (which, in turn, controls the toughness), all surface defects are cut out of ingots or billets, inspection is much more stringent—to mention some of the major differences.

The earliest alloy steels used those alloys then available; after World War I useful steels were developed with alloying metals that were formerly unavailable or rare. (1) Chromium alloy steels were made commercially into hard grinding equipment by Julius Baur in 1869, and made their debut in structures in the arch members of the Eads bridge (1874) across the Mississippi river at St. Louis, Mo., and they now enter many steels for machine parts. The high chromium steels are corrosion and oxidation resistant (*see* STAINLESS STEEL). (2) Nickel, now another common constituent of alloy steels, was first incorporated in steels by Marabeau; the properties were described in 1889 by James Riley. Nickel steel was adopted by the U.S. navy for armour plate in 1891; it is said that its first application in the mass-production industries was some armour plate rolled into small bars for bicycle chains. (3) Tungsten is the essential element in the air-hardening tool steel of R. F. Mushet (1871). This was the precursor of modern high-speed tool steel (*q.v.*). It is also used in magnets and steels for extra high-temperature service. (4) Molybdenum, its chemical cousin, was unavailable until large U.S. deposits began producing in Colorado about 1918. In addition to being a substitute for tungsten, molybdenum is also a most important element, in fractional percentages, in engineering alloy steels. (5) Manganese formed the first high alloy steel, 10% being added by Robert (later Sir Robert) Hadfield in 1882 to form a very tough steel of unique properties, largely used in items such as power-shovel dipper teeth that must resist tremendous battering. Low manganese steels were the product of 1920–30 and were substituted in many uses for the more expensive chromium and nickel steels. (6) Silicon steels, especially useful for electrical transformers and other equipment, were devised in 1889 by Hadfield. (7) Vanadium and chromium-vanadium steels were investigated in England by Arnold and J. Kent-Smith at the turn of the century; the latter, at Canton, O., in 1907 made the first alloy steel by the open-hearth process for the Ford Motor Co., and this company pioneered the use of alloy steels in mass production. (8) Steels containing

a fractional percentage of copper, for atmospheric corrosion resistance, also are a pre-World War I product.

The eight common elements referred to above, in various percentages and combinations, to say nothing of an equal number of less commonly used alloying metals, may be used to manufacture an infinite variety of steels. Since the beginning of the 20th century, literature about them has accumulated in a formidable mass. A group of metallurgists led by Edgar C. Bain systematized much of the existing information. Commercial requirements of both producers and consumers also demanded a limitation of types. The American Society of Automotive Engineers led the way in 1911 by adopting chemical specifications for 7 carbon and 11 alloy steels. Since that time the list has been extended greatly, comprising 90 standard alloy steels in the 1960s. The American Iron and Steel institute also publishes a list of standard alloy steels that comprises about 75 grades, containing manganese, nickel, chromium, molybdenum and vanadium (single or in combination). This list includes a few boron-treated steels using smaller amounts of alloys. There are also about 38 standard types of wrought stainless steels, and many varieties are available in cast form. Many large consumers and the United States government have their own compositions.

Bain's scientific classification gave logic to the practical conclusion that many of the varieties are interchangeable. Users are slow to discard a steel that has served well in the past, fits into an existing heat-treatment schedule and is approved by the staff, but economics of product manufacture slowly forces the adoption of the cheapest suitable materials. This generally means steels of lower and lower alloy content. Such a change was forced on all users during World War II by the disruption of alloying metal production and the priority demands for arms and ordnance. In the United States it brought low-alloy steels whose hardenability was largely increased by adding a very small amount of boron (about  $\frac{1}{2}$  oz. per ton). Aside from war stringencies, the engineering alloy steels made in the U.S. contained nearly 3% of total alloy in 1920 and only slightly over 1% after World War II.

While U.S. industry relies upon chemical composition (plus hardenability, as described below) to characterize its alloy steels, Europeans generally depend more on the strength of a steel after normal heat treatment, and give the steelmaker more latitude in the selection of an appropriate analysis.

**General Influence of Alloys.**—A statement frequently heard is that alloy steels are valuable chiefly because they may be hardened and strengthened by heat treatment without incurring the brittleness associated with hardened plain carbon steel. Further it is frequently said that to be economically justified, the alloy steels should be used in the quenched and tempered state. It will be shown below that the true function of alloys in the engineering or machine steels is to get high strength and toughness, or hardness and toughness, simultaneously, either more easily than they can be had in carbon steels, or in sizes and shapes in which they cannot be had in carbon steels. Certain alloys also impart unique properties to carbon steels (such as high chromium for corrosion resistance or high manganese for battering abrasion), but in defense of the plain carbon steel it may be said that high strength, hardness and toughness are not the sole property of alloys. Thus, the intensity of hardening primarily depends on carbon content. No alloy steel has been discovered that can be made harder than properly quenched carbon steel containing 0.75% or more carbon (measured as C-67 by the Rockwell instrument, wherein hardness number is inversely proportional to size of indentation by a loaded diamond point). However, some highly alloyed tool steels can be hardened to Rockwell C-70.

Since steel, as it has been defined, is essentially an alloy of iron and iron carbide, the alloys present in it can be located in one or more of three possible phases or microconstituents: (1) in solid solution in the iron—the alpha iron or ferrite; (2) combined with carbon, either replacing some iron in the iron carbide or forming a carbide of its own; (3) combined with oxygen, nitrogen or sulfur in nonmetallic, insoluble inclusions. Rarely does one alloy act in one way alone; partition among (1), (2) and (3) depends upon the amount of alloying element or elements, amount of carbon and

temperature. However, some alloys, such as nickel and manganese, act notably to form solid solutions and strengthen the ferrite. Others act notably to enter and form carbides, as vanadium and molybdenum. Titanium is the outstanding example of the elements in category (3).

**Strong Structural Steels.**—Alloys falling in category (1) are particularly useful in improving the mild steels used for plates and structural shapes. These steels are usually fabricated by the user as they are delivered to him from the rolling mill, without further heat treatment. In fact, they must be rather insensitive to heat treatment, else flanging and especially welding will produce hard regions ruinous to the tools that punch or cut them, or regions lacking in required ductility. Extra strength and correspondingly lighter sections, such as are desirable for a long-span bridge or for railway car bodies, can, of course, be had by increasing the carbon content, but this aggravates the problem of hardness. The alternative is to add alloys that enter into solid solution with the iron and so strengthen the ferrite, which, by the way, is the major microconstituent of these low carbon steels. Bain lists these alloying elements in the order of their influence as ferrite strengtheners from strongest to weakest, as phosphorus, silicon, manganese, nickel and that portion of the chromium that is not combined with carbon. Each of them is used and in various combinations in commercial tonnage steels.

Nickel steel was undoubtedly the first, used for long-span bridges, 3½% of that element greatly improving the tensile properties and doubling the impact strength. Higher strength steels are receiving more and more acceptance in many structural applications. These include high strength low alloy steels and heat-treated constructional alloy steels, with strength levels from 35,000 to 100,000 lb. per square inch. Part of this acceptance is due to the design flexibility that is possible. Equally important, higher strength can lead to weight reduction and savings in cost of the erected frame. These strong steels, when weldability is important, must have low carbon content.

After 1940 there was a notable trend toward welded rather than riveted structures (ships, tanks, penstocks, bridges), and the problem of steel's weldability correspondingly arose. An early application of alloy steel, used for its strength in welded spheres containing hydrocarbons kept liquid at very low temperature, led to a disaster costing 128 lives in Cleveland, O., in 1944. Nor is plain carbon steel in rigid structures immune to catastrophic cracking, as witness the 25 or more major failures of welded "Liberty" ships during 1942-45 and 14 canal bridges in Belgium in 1947-50. Extensive investigation determined that for welded ships a fine-grained, low-alloy steel containing less than 0.2% carbon, 1% to 1.35% manganese and no more than 0.04% silicon has good toughness and the ability to stop the spread of an incipient crack at subzero temperatures. This crack-stopping ability is the characteristic necessary for safe performance. It is related to a low transition temperature, mentioned below.

**Hardenability of Alloy Steels.**—Alloys are, of course, of most importance to heat-treatable steels, for an alloy bar will harden under similar circumstances much more deeply than a comparable carbon steel bar. When steels are heated above their critical points—a range of about 725° to 825° C.—the crystal structure of alpha ferrite is transformed into a new one called gamma iron, which has far greater solubility for carbide. This high-temperature solid solution of the carbides in gamma iron is called austenite. On slow cooling the reverse action takes place at about the same temperature range, and the annealed, fairly soft and ductile steel is reconstituted, except that the process may have refined the grain. On more rapid cooling the precipitation of carbide from austenite is delayed—a little time is necessary for the action to incubate and then to proceed to completion—and occurs at a somewhat lower temperature. On very rapid cooling, as when quenching a small piece in cold water, austenite is trapped unchanged down to about 150° C. but then changes almost completely and almost instantaneously to a very hard structure called martensite, which seems to be alpha iron (ferrite) in which the iron carbide is dispersed in almost molecular particles. This is the essence of the hardening action. (For a fuller account of the

metallographic change see IRON AND STEEL INDUSTRY: *Steel Metallurgy*.)

Plain carbon steels have a low hardenability, in the sense that if a 1½-in. round bar is quenched in cold water only the outer layers of the steel are cooled rapidly enough to transform at low temperature into martensite; the inner core, cooling more slowly, is transformed at high temperatures near the critical into a much softer entity, a coarser mixture of laminated ferrite and carbide. The outer surface may be intensely hard, even the maximum possible for the carbon content of the steel, but the penetration of that hardness is low. To harden the bar more deeply, the cooling rate at the surface must be faster, so the deeper regions of the steel may cool rapidly enough to escape the high-temperature transformation; even the most drastic quenching, as in brines or water sprays, may be insufficient for complete hardening.

Fortunately, the presence of all the alloying metals except cobalt slows up both the solution of carbides in the austenite on heating, and their precipitation on cooling. This means that alloy steels do not need to be cooled nearly so rapidly in order for the austenite to be trapped and transformed at about 150° C. into hard martensite. Alloy steels therefore have a higher hardenability. Given an equal quench and an equal-sized bar, the alloy bar will harden much more deeply than the carbon steel bar of the same carbon content; or it may be satisfactorily hardened in a much milder quenching bath, as in oil or even in still air, with correspondingly less warpage and danger of cracking. As an example, the presence of 1½% nickel and 0.6% chromium doubles the hardenability of a 0.45% carbon steel. Bain's list of the relative potency of alloys in this respect follows: very strong, vanadium; strong, molybdenum and tungsten; moderate, chromium, manganese, silicon; mild, copper, nickel, phosphorus. (At the top of this list would now be placed boron.)

**Toughness of Alloy Steels.**—Certain of the alloys have still another beneficial effect—that of refining the grain. According to the laws of crystallography, certain favoured austenite grains should grow at the expense of their neighbours, with the result that the hot steel should become coarser grained with longer and longer stay at higher and higher temperature. But first a considerable time is necessary to dissolve complex and sluggish carbides in the austenite; many seem to have a central particle that resists dissolution, and these refractory particles disseminated through the metal effectively prevent the natural grain growth of the solid solution. The advantage is that a fine-grained austenite, when quenched and tempered, has a very desirable degree of toughness. Bain's list of grain refining elements, arranged according to their effectiveness, is: titanium (very strong), vanadium, molybdenum, tungsten, chromium and manganese (mild).

Aluminum, added to the metal in proper small quantity in a properly deoxidized steel, apparently reacts with traces of oxygen and nitrogen dissolved in the steel and precipitates out as a cloud of insoluble particles in the solidifying steel. These inclusions are even more effective obstructions to austenite grain growth. Such fine-grained steels are popular in the United States. They are especially useful in low carbon, carburizing steels. In the carburizing operation, machined steel parts can acquire a high carbon skin or case, say 0.05 in. deep, in five hours' exposure to a highly carbonaceous gas at 1,700° F. (about 925° C.). Even after such a long and high heating the austenite remains so fine in grain size that the parts can be quenched directly from the carburizing heat to harden the high carbon case, the inner portions remaining fine grained and tough. (See also HEAT-TREATMENT.)

The toughness of alloy steels, or the ability to absorb rapid blows, is also improved by the circumstance that those containing the carbide-forming elements listed above may be tempered or reheated after quenching to considerably higher temperatures than carbon steels of the same carbon content and still retain the hardness of the plain carbon steel, quenched and tempered at a lower temperature. Evidently the sluggish diffusion of alloying elements, trapped in solution in the freshly quenched martensite, requires a higher temperature and a longer time before the complex carbides can re-form, in comparison with the formation of simple iron carbide (Fe<sub>3</sub>C) by diffusion of trapped carbon. Since the toughen-

ing due to tempering is largely a matter of relieving the high internal stresses in freshly quenched steels, and since this stress relief is greater at higher temperature, it can be seen why alloy steels, after proper heat treatments, may give metal that is strong, hard and unusually tough.

Toughness, as the term is used in the preceding paragraph, is measured by a single-blow Charpy impact test, wherein a 10-mm. square bar, with carefully machined V-notch on one side, is struck by a swinging hammer, and the energy absorbed in breaking the small notched bar is measured. Various combinations of alloys respond differently to this test when quenched and tempered to the same hardness (and strength). For example, A.I.S.I. 5145 (0.45% C and 0.8% Cr) has 55 foot-pounds (ft.-lb.) at 70° F. (21.11° C.) and 30 ft.-lb. at -100° F. (-73.33° C.). A.I.S.I. 4340 (0.4% C, 1.75% Ni, 0.8% Cr and 0.25% Mo) has 70 ft.-lb. at 70° F. and 60 ft.-lb. at -100° F. (Both these had equal hardness: 35 on the Rockwell C-scale.) Such circumstances indicate why steels containing considerable alloy are favoured for use at low temperatures and for shock-resisting pieces such as axles and cannon. Generally speaking, the carbon steels have high transition temperatures, around 70° F. (above which high impact strengths and fibrous fractures occur, and below which low impact strength and rapid extension of cleavage or brittle fractures occur). Low-alloy steels, like the ship plate mentioned above, have a transition temperature of -10° F. Higher engineering alloy steels such as A.I.S.I. 4340 have transition temperatures of -100° to -200° F. The austenitic stainless steels containing 18% Cr and 8% Ni have transition temperatures around that of liquid air.

The sluggish changes in the microstructure of the complex alloy carbides during heat treatment are utilized in steels for high-temperature, high-pressure equipment. Stable carbides enable the hot metal to resist creep at high temperature. The American Society of Mechanical Engineers' boiler code tentatively proposed a working stress of 5,750 lb. per square inch for plain carbon steels at 900° F. (about 480° C.) and 10,000 lb. per square inch (nearly double) for the same steels plus 0.5% molybdenum. To increase corrosion resistance, chromium is also added; 1.25% Cr and 0.5% Mo, or 2.25% Cr and 1% Mo are favoured compositions for pressure vessels serving at moderately high temperatures.

**Tool Steels.**—Since alloying elements, either in solid solution with iron or in the form of complex carbides, tend to strengthen and harden steel and also to bear up under heat without softening as readily as a plain carbon steel, cutting and forming tools are made of a family of complex alloy steels each suited for its particular duty. (See TOOL STEEL.) Excellent hardenability is desirable for forging or hot forming dies, for example, which must often be hardened in large blocklike masses; they must also be hard, to resist wear, and tough, to withstand blows. The tip of a lathe tool, cutting at a high rate of speed, is heated almost red hot by friction from the chip; it must retain useful hardness. Generally speaking, tungsten (up to 18%) and molybdenum (a useful substitute, at least in large part) are ordinarily depended upon for retention of hardness even when hot. Chromium (up to 12%) and carbon (up to 2%) give maximum hardness and wear resistance at ordinary temperature. Vanadium is the traditional element for refining the metallic grain size and thus promoting shock resistance. Manganese (up to 3%) is the main alloying constituent in dies that must be hardened without measurable change in size or shape—the so-called nondeforming steels.

**Interchangeability of Alloy Steels.**—A definite combination of strength, hardness and toughness may be secured from any one of a large number of alloy steels, provided the size is not too large and the heat treatment properly adjusted.

There is a definite trend toward the use of low alloy steels for machine parts that are to operate at normal temperatures, in both the United States and Great Britain. The trend is especially strong in the smaller sizes of forgings or machined gears, where adequate penetration of hardness may be secured by not too drastic quenches. For devices that must operate at extremes of temperature and for massive forgings, steels with higher content of alloys and long-continued heat treatments to permit the sluggish reactions are necessary.

**Large Forgings.**—A rough forging for a 240-mm. howitzer weighs 30,000 lb., and the original ingot would probably weigh 75,000 lb. Rotor forgings for very large electrical generators may weigh over 100,000 lb. In such massive parts, good steelmaking practices are of prime importance; the basic process is used, since it can drive the impurities sulfur and phosphorus down to 0.015% each. To avoid tiny internal bursts or flakes, the gas content, especially hydrogen, must be reduced to as near zero as possible. The development of vacuum degassing techniques for removing gases from molten steel has largely solved this problem. Extreme homogeneity and cleanliness will prevent small segregations of alloy within the metal that prevent uniform hardening reactions and introduce large internal stresses; nonmetallic inclusions ("dirt") are also dangerous stress raisers. U.S. specifications for gun tubes say nothing about chemical composition. The ordnance manufacturer can choose the alloy he thinks best for the required yield strength, reduction of area at fracture (ductility) and Charpy impact value at -40° F. (toughness). Test pieces are cut in a direction transverse to the axis of the gun so as to prove its ample strength against bursting. Principal stresses in generator rotors are centrifugal, from the high speeds of 3,600 r.p.m. A steel of 0.3% C, 2.5% Ni, 0.5% Mo and 0.5% Cr or 1% Mn has been widely used in the United States. German practice favours considerably less nickel and molybdenum.

**Gear Steels.**—As a specific application of the above general principles, the problems of gear manufacture may be considered, for the choice of steel and its treatment depend very intimately on the design of the part and its intended duty. The high-duty herringbone gear sets used on turbine-driven propeller shafts, for example, are marvels of precision; they are of cast alloy steels heat treated to relieve internal stresses and ensure dimensional stability as well as induce as much hardness for wear resistance as is consistent with machinability. The steels contain 0.5% to 0.6% carbon, but alloys are necessary to give proper depth of hardening and fine grain size. Examples are 1.25% manganese plus one or more of the elements molybdenum (0.3%), nickel (1%), chromium (0.5%) and vanadium (0.15%). In large sections a quenched and tempered chromium-nickel-molybdenum cast steel will have the following physical properties indicating medium strength and hardness with great toughness: yield point 105,000 lb. per square inch; tensile strength 135,000 lb. per square inch; elongation 20% in 2 in.; reduction of area 64%; Rockwell hardness C-32.

In the smaller gears utilized for automobile transmissions and rear axle drives the mass effect or deep hardening effect is not so necessary. Requirements are very diverse and exacting, and these together with the desire to save weight, and therefore to have gears as small as possible, have preserved this field to alloy steels. The original conception of a gear tooth was that it should have a hard surface to resist wear and a tough centre or core to resist impact. Following this idea, gears were cut from forged and annealed blanks of low carbon alloy steel (less than 0.2% carbon); the machined gears were then carburized by heating in contact with carbonaceous solids or gases. Subsequent heat treatment was at times rather intricate, consisting of a lower-temperature quench to refine the low carbon core, a lower-temperature quench to harden properly the high carbon surface, and a tempering to improve the toughness. Today a variety of steels are available, suitable for any designer's requirements, where he balances cost (alloy content, machinability and heat treatment schedule) against strength desired to carry the loads on the gear tooth, and toughness against impact loadings.

Carburizing steels low in carbon gives an outer surface containing 0.9% to 1% carbon, and since surface hardness of the quenched gear depends on carbon, rather than on alloy content, gear teeth can be made file hard—that is, too hard to be bitten by a testing file whose hardness is Rockwell C-65. Experience has also proved that maximum resistance to abrasion is secured from such high carbon cases on steel containing chromium or molybdenum carbides. One serious objection to the practice outlined above is the cost of heat treatment after carburization, and this has been attacked by the use of fine-grained steels that may

be quenched directly from the carburizing heat and still possess a fine structure and considerable toughness. This practice was fairly common with the 1% chromium, 0.15% vanadium steels, which are inherently fine-grained, before the special fine-grained steels were regularly produced by the steel mills.

High-speed transmission gears in automobiles must operate without much noise, and this requires a degree of accuracy of shape on the order of 0.0005 in. Warpage increases with the depth of carburization, so shallow cases were tried to give quieter gears. This was successful, but the hard case tended to flake off, due to fatigue failure of the weaker low carbon metal at junction of case and core. To strengthen this metal it was necessary to increase carbon content, and the result was that in American automobiles after about 1950 the great majority of transmission gears were of steels that used to be called oil quenching gear steels, high enough in carbon and alloy to quench to a file hard surface without carburization. An upper carbon limit is set by the demands of reasonable machinability. Whereas the old oil-quenched gears were heated in molten lead for quenching (in order to avoid any trace of decarburized soft skin), the more modern practice is to hold them in a cyanide bath at 815° C. for about 25 minutes, which is enough to induce a 0.002-in. case of carbides and nitrides, exceedingly hard and wear resistant, or to heat them in a controlled gas of carburizing and nitriding nature.

**Austenitic Steels.**—Hadfield's cast 10% manganese steel, discovered in 1882, was remarkable in that it did not harden on quenching. It is, in fact, an austenitic alloy, in the sense that the expected change from austenite solid solution to hard martensite does not occur at 200° C., but the quenched austenite is very stable at room temperature. Cobalt, but especially nickel, has similar effects. One result of this is that the most useful of the stainless steels, known as 18-8 and containing 18% chromium and 8% nickel, is unhardenable by quenching.

One characteristic of these commercial austenitic steels is that the austenite is not entirely stable. The small plastic movements in high manganese steel, associated with battering or attempted cutting, permit the martensitic reaction to occur in those restricted regions, causing intense hardness—hence their wear resistance in rough service. This is a favourable reaction, but many of the 18-8 steels are put into petroleum stills operating between about 450° and 850° C., and this temperature gives enough thermal agitation to the atoms so that chromium carbides form from the austenite solid solution, unfortunately not in a cloud throughout the mass to key and strengthen the metal, but localized at the grain boundaries, seriously depleting the surrounding matrix of its chromium necessary for corrosion resistance. This deterioration of 18-8 (even by the heat of welding) is prevented by introducing minor amounts of strong carbide-forming elements, like molybdenum, titanium or columbium. The latter two, especially, form carbides that are so insoluble in austenite that they act as inert nonmetallic inclusions.

**Ultrahigh Strength Steels.**—The continuing need for higher and higher strength-to-weight ratios in alloys used in aerospace vehicles has, since 1960, sparked the development of a new class of exceptionally strong steels. Termed "ultrahigh strength" steels, these grades have, by definition, yield strengths of 220,000 lb. per square inch and above. Steels in this category include A.I.S.I. 4340 and its modifications, H11 and H13 (5% Cr high-speed steels), A.I.S.I. 410, 420 and 431 (martensitic stainless types), and AM-355 and PH 15-7 (austenitic precipitation hardening stainlesses). Of special interest are "maraging" steels which contain 18% to 25% nickel. On heating to the 1,000° to 1,100° F. (590° C.) range and slow cooling, they harden to yield strengths of 250,000 to 300,000 lb. per square inch with little distortion.

**Electrical Sheet.**—The foregoing account relates primarily to strength of alloy steels. Other properties are often of more importance, such as corrosion resistance (see STAINLESS STEEL) and electrical properties. A prime example of the latter is silicon steel transformer sheet—really a very low carbon (0.01%) alloy of iron with 3.25% silicon, plus tiny additions of certain impurities such as nitrogen to control directional crystallization. The silicon goes into solution in the iron and this ferrite with cubic crystal-

linity has great magnetic superiority in one direction. The problem is to make sheet by the ton in which the tiny crystals—ordinarily oriented randomly—are lined up or regimented. The commercial method was discovered in 1933 by Norman P. Goss—a series of cold reductions each followed by annealing in hydrogen. The great utility of such silicon iron is illustrated by the fact that a 1.5-kva., 7,200-volt transformer made in 1935 weighed 275 lb.; in 1945 it weighed 120 lb. See IRON AND STEEL INDUSTRY; ALLOYS; and the various types of steels under their own headings; see also references under "Steels, Alloy" in the Index.

**STEELYARD, MERCHANTS OF THE,** were merchants of the Hanseatic League (*q.v.*) who resided at the League's London establishment, or *kontor*, known as the Steelyard (probably from Low German *stålgaard*, a courtyard for the display of sample goods). Merchants from Cologne and other Rhineland towns had a privileged position in London before the Norman Conquest. In the 12th century their importance grew rapidly; as the "Cologne Hanse" (or guild) they had their own hall (the nucleus of the future Steelyard) and won protection and various rights from Henry II and Richard I. The arrival in London in the 13th century of merchants from Lübeck, Hamburg, and other towns of eastern Germany at first led to friction between Rhinelanders and "Easterlings." But by 1282 they had coalesced into one hanse and became an integral part of the Hanseatic League, which came into being at that time or shortly afterward.

The Steelyard, the area granted to the German hanse, was off Thames Street, near Blackfriars, and had a frontage on the river, where the merchants anchored their ships. In this area, virtually an extraterritorial concession, the merchants were completely exempt from English jurisdiction and were governed by an alderman and a council of 12, who administered German law. They had a hall, living rooms, and warehouses, and a court (the Steelyard proper) for the display and sale of goods.

English traders increasingly resented the favoured position of the Steelyard merchants, who were exempt from the usual restrictions laid on foreign traders (they could engage in retail trade and deal directly with other foreigners) and paid (for instance, on exported cloth) customs dues often lighter than those imposed on the English themselves. But while their loans were of value to the English crown and their trade important for the English economy, and while England lacked sufficient shipping to capture the carrying trade, the rising clamour against them was ignored. However, by the reign of Elizabeth I the relative strength and advantage had passed decisively to the English, and in 1598 Elizabeth closed the Steelyard.

See F. Schulz, *Die Hanse und England von Eduards III bis auf Heinrichs VIII seit* (1911); also articles by K. Engel, M. Weinbaum, and G. A. Löning in *Hanseatische Geschichtsblätter* for the years 1913, 1928, and 1942-43, respectively.

**STEEN, JAN HAVICKSZ** (1626-1679), after Rembrandt, the most varied and penetrating of the Dutch genre painters, was born at Leiden in 1626. His father was a brewer, and at various times Steen himself was a brewer and tavern keeper. He was a founder-member of the Leiden Guild of St. Luke in 1648. In 1649 he settled in The Hague and married Margareta van Goyen, daughter of the landscape painter. He moved to Delft in 1654 and to Haarlem in 1661. In 1670 he was back in Leiden; he married a second time in 1673. He was buried in Leiden, Feb. 3, 1679.

Steen's master was the Utrecht historical painter Nicolaus Knupfer, but there is little obvious influence of Knupfer even in his occasional history pieces, such as "Samson and Delilah" (Cologne) or the "Adoration of the Shepherds" (Rijksmuseum, Amsterdam). He is first and foremost a genre painter, heir to the "low life" tradition of Adriaen Brouwer and his school. In

BY COURTESY OF THE VICTORIA AND ALBERT MUSEUM

"DOCTOR'S VISIT" BY JAN STEEN. THE WELLINGTON MUSEUM, LONDON

style and content he looks back on the one hand to the great early masters of genre, Hieronymus Bosch and Pieter Brueghel, and on the other adheres to the polished, colourful manner of his own generation, comparing favourably with Gerard Ter Borch and Gabriel Metsu in his delicacy of touch and his skill in rendering light and texture. However, his typical pictures are scenes of revelry, displaying a huge zest for living and a humour that ranges from subtlety to the crude or grotesque, or quieter scenes that yet pass a satirical comment on human character and behaviour, such as the numerous versions of "The Doctor's Visit." Often the coarse but engaging features of the painter himself grin familiarly at the spectator, inviting him to concur in this hilarious view of the world. The earthy jollity in Steen is balanced by an intellectual and literary element, with an extensive use of allegory, that is unique among the Dutch genre painters and gives a peculiar piquancy to his art.

See C. Hofstede de Groot, *Catalogue of Dutch Painters*, vol. i (1907); F. Schmidt Degener and H. E. van Gelder, *Jan Steen*, Eng. trans. (1927).

**STEEVENS, GEORGE** (1736–1800), English Shakespearean scholar, author of the first variorum edition, was born at Poplar on May 10, 1736, the son of a captain, later a director, of the East India company. He was educated at Eton and King's college, Cambridge, but left without taking a degree. He acquired a house on Hampstead Heath where he built up a great library, including over 30 early Shakespearean quartos and many Hogarth prints. Every morning he walked into London, visited his friend Isaac Reed, made a round of the booksellers and walked back to Hampstead. In 1766, when he was only 30, he published a reprint of 20 of the quarto editions of Shakespeare's plays, a notable achievement, especially at that time when the value of the quartos was not fully recognized. In 1773 he published a ten-volume edition of Johnson's *Shakespeare*, more fully annotated and including excerpts from other commentators. (Johnson's contributions to the edition were slight.) This therefore was an attempt at a variorum edition. In 1793, however, Steevens was persuaded by

his jealousy of Edmund Malone to publish an edition of 15 volumes in which he used his wide knowledge of Elizabethan literature to offer many useful parallels from writers contemporary with Shakespeare. It is Isaac Reed's 1803 reissue of this edition, with additional notes left by Steevens, which is known as the first variorum edition.

Steevens was a learned man of an acrid and sometimes malignant humour. His practice of writing notes on obscene passages and expressions, which he signed with the names of clergymen he disliked, earned him the title of the Puck of commentators. He was one of the expositors of the Chatterton-Rowley and Ireland forgeries. He died at Hampstead on Jan. 22, 1800.

See D. Nichol Smith, *Shakespeare in the 18th Century* (1928).

**STEFAN, JOSEF** (1835–1893), Austrian physicist, who made original contributions to the kinetic theory of gases, hydrodynamics, and radiation, was born on March 24, 1835, at St. Peter near Klagenfurt and died on Jan. 7, 1893, in Vienna.

Stefan was educated in the University of Vienna, where he became doctor of philosophy in 1858, then *Privatdozent* in mathematical physics, in 1863 professor ordinarius of physics, and in 1866 director of the Physical Institute. He was a distinguished member of the Vienna Academy of Sciences, of which he was appointed secretary in 1875. Before Stefan's work, G. R. Kirchhoff had already described the perfect radiator as the "perfectly black body," namely, one that absorbed all the radiation that fell on it and reflected none, but emitted radiation of all wavelengths. Stefan showed empirically in 1879 that the radiation of such a body was proportional to the fourth power of its absolute temperature, a relationship since known as Stefan's Law or as the Stefan-Boltzmann Law after it had been deduced by L. Boltzmann in 1884 from thermodynamic considerations. Stefan's Law was one of the first important steps leading to the understanding of black-body radiation from which the quantum idea of radiation sprang (see further **HEAT: Radiation: Relation Between Radiation and Temperature**). (D. McK.)

**STEFANSSON, VILHJALMUR** (1879–1962), Arctic explorer, discovered large areas in the Canadian Arctic and became an authority on Eskimos. He was born on Nov. 3, 1879, at Arnes, Man., of Icelandic parents. He graduated from the University of Iowa and later studied theology and anthropology for three years at Harvard University. After two archaeological voyages to Iceland in 1904 and 1905, he turned to Arctic research, and in 1906–07 he visited the Canadian Arctic for the first time as ethnologist on an expedition to the Mackenzie River delta. The expedition ship, approaching from the west, was unable to penetrate the ice beyond Point Barrow, so Stefansson, who had traveled alone overland, never joined the expedition. Instead he spent a year living with the Eskimos, acquiring an intimate knowl-

STEFANSSON. PHOTOGRAPHED ABOUT 1930

edge of their language and culture, and forming the belief, which he put into practice during his later travels, that Europeans could "live off the land" in the Arctic by following the pattern of Eskimo life. From 1908 to 1912 he and R. M. Anderson carried out ethnographical and zoological studies among the Mackenzie Eskimo and the Copper Eskimo of Coronation Gulf, including some groups hitherto unknown to Europeans.

He next led an expedition sponsored by the Canadian government, spending five consecutive years (1913–18) north of the Arctic circle, exploring the western Canadian Arctic and discovering Borden, Brock, Meighen and Longheed islands. His knowledge of the Canadian Arctic gave rise to his profound belief in

the potential economic importance of the area. In 1932 he became adviser on northern operations for Pan-American Airways. In World War II he served the United States government in an advisory capacity, surveyed defense conditions in Alaska, and prepared reports and manuals for the armed forces, becoming Arctic consultant to the Northern Studies program at Dartmouth College, Hanover, N.H., from 1947. He died in New York, Aug. 26, 1962. His principal publications are: *My Life with the Eskimo* (1913); *The Friendly Arctic* (1921); *The Northward Course of Empire* (1922); *The Adventure of Wrangel Island* (1925); *The Standardization of Error* (1928); *Unsolved Mysteries of the Arctic* (1939); *Greenland* (1942); *Arctic Manual* (1945); *Discovery* (1964). (L. M. Fs.)

**STEFFANI, AGOSTINO** (1654–1728), Italian composer, singer, cleric, and diplomat, celebrated in his own time for his cantatas for two voices, which are still remembered. He was born at Castelfranco on July 25, 1654. He studied music in Venice, Rome, and Munich, where he served the elector of Bavaria from 1674 to 1688, becoming by 1681 director of chamber music and the object of great favours. In spite of this, he left Munich and entered the service of the duke of Brunswick, later elector of Hanover, where he remained until his death. After some years he ceased to be musical director, however, and entered upon a new career: while continuing to practise music, he became important as a diplomat, going on several missions and acting for a short time as ambassador in Brussels. It was he who induced Handel to settle in Hanover and hence, indirectly, in London, when the new elector became King George I. Steffani was ordained in 1680 and later became papal protonotary for north Germany, with the status of bishop. He died at Frankfurt am Main on Feb. 12, 1728. He composed about 20 operas, most of them before 1700. It was, however, his numerous chamber duets in cantata form—following, with considerable melodic and structural distinction, the models of L. Rossi, G. Carissimi, and A. Stradella—that won for Steffani a European reputation; more than 100 of these are known. (N. Fo.)

**STEFFEN, ALBERT** (1884–1963), Swiss novelist and dramatist, was one of the leading writers of the anthroposophical movement founded by Rudolf Steiner (*q.v.*). Steffen was born at Murgenthal on Dec. 10, 1884. His early works were compassionate messages of alarm at the disastrous effects of modern technological civilization and secularized thought in human relations. Moved by these problems, he joined the anthroposophical movement in 1907, settling at its centre in Dornach, near Basel. (Steffen was later president of the Anthroposophical Society and was editor of its review, *Das Goetheanum*.) From that time his numerous writings became visions of a world permeated by metaphysical powers of good and evil, as revealed in old and esoteric European and Asiatic traditions. His novels include *Die Erneuerung des Bundes* (1913) and *Aus Georg Archibalds Lebenslauf* (1950); his plays, *Hieram und Salomo* (1927), *Das Todeserlebnis des Manes* (1934), and *Barrabas* (1949; Eng. trans., *Christ or Barrabas?*, 1950); and his essays, *Der Künstler zwischen Westen und Osten* (1925; Eng. trans., *The Artist Between West and East*, 1946). *Buch der Rückschau* (1939) is autobiographical. Steffen died at Dornach on July 13, 1963.

**BIBLIOGRAPHY.**—A. von Sybel-Petersen, *A. Steffen* (1934); *Das A. Steffen-Buch*, ed. by P. Bühler (1944); F. Hiebel, *A. Steffen* (1964). (A. Bx.)

**STEFFENS, HENRIK** (1773–1845), Danish philosopher and physicist, combined scientific ideas with German idealist metaphysics. He was born on May 2, 1773, at Stavanger, Nor., but spent his early years at Copenhagen, where he attended the university. He later studied at Kiel, Jena, and Berlin and by 1799 was an established figure in German literary and philosophical circles and on friendly terms with Schelling, Goethe, and Friedrich Schleiermacher. After publishing *Beiträge zur innern Naturgeschichte der Erde* (1801), he took up an academic career, beginning as a lecturer at Copenhagen in 1802 and becoming professor of mineralogy at Halle in 1804 and professor of physics at Breslau in 1811. Steffens spent almost all his adult life in Germany, which he regarded as his home, and was a fervent sup-

porter of German nationalism. He fought with the Prussian Army against Napoleon in 1813 and 1814. Professor of physics at Berlin from 1832, he died there on Feb. 13, 1845.

Steffens did much sound scientific work as a physicist, but as a philosopher he was characterized by a fondness for using scientific fact as a basis for the construction of fanciful analogies and quite arbitrary metaphysical conclusions. His exposition of a philosophy of nature in *Grundzüge der philosophischen Naturwissenschaft* (1806) showed a typical combination of profound scientific knowledge and Schellingian speculation. He also wrote *Anthropologie*, 2 vol. (1824); an autobiography, *Was ich erlebte*, 10 vol. (1840–44); and some novels and poetry.

See I. Möller, *Henrik Steffens* (1948).

**STEFFENS, (JOSEPH) LINCOLN** (1866–1936), U.S. journalist, lecturer, and political philosopher, was a leading figure among the writers whom Theodore Roosevelt called muckrakers (*q.v.*), but his work was closer to documented sociological case study than mere sensational exposure. He was born in San Francisco, Calif., on April 6, 1866. After attending the University of California, he did graduate study with Wilhelm Wundt in Leipzig and with Jean Martin Charcot in Paris, which confirmed his basic positivist orientation. During nine years of New York newspaper work, Steffens discovered abundant evidence of corruption of politicians by businessmen seeking special privileges. In 1901 he became managing editor of *McClure's Magazine* and soon began to publish the influential articles later collected as *The Shame of the Cities* (1904). Many nationwide lecture tours won him recognition as an American Socrates. He raised rather than answered questions, jolting his audience by comic irony rather than moral indignation into awareness of the ethical paradox of private interest in public affairs. He revealed the shortcomings of the popular dogmas that connected economic success with moral worth and national progress with individual self-interest by showing that the Horatio Alger hero often won his position by corrupting the community—and himself.

Developments in Mexico and Russia turned Steffens' attention from reform to revolution. After a trip to Petrograd in 1919 he wrote a friend, "I have seen the future, and it works." His unorthodoxy lost him his American audience during the 1920s; he continued to study revolutionary politics in Europe and became something of a legendary character for the younger expatriates. After the great success of his *Autobiography* (1931), he supported many Communist activities but refused identification with any party or doctrine. He died on Aug. 9, 1936. His characteristic achievement, both as writer and as lecturer, was in persuading people to examine for themselves the character of contemporary civilization.

His *Letters* were edited by Ella Winter and G. Hicks, 2 vol. (1938). (R. D. H.)

**STEIERMARK** (STYRIA), a *Bundesland* (federal state) of Austria, borders on Yugoslavia, which lies to the south. Area 6,326 sq.mi. (16,384 sq.km.). Forming the southeastern part of Austria, the *Bundesland* shares in two of the country's main physical components, the Alps and the southeastern hill country. The principal regional division into Upper Steiermark and Lower Steiermark is based on this physical distinction. Upper Steiermark stretches in the north from the Limestone Alps to the eastern groups of the Central Alps and also embraces the valleys of the Salza, Upper Enns, Mur, and Mürz. Lower Steiermark is an upland and hill country consisting of: the middle Mur Valley with Graz "bay" in the centre; the Koralpe and Packalpe, which rise to just over 6,500 ft. (2,000 m.) in the west; and a hill country of uplifted Pliocene gravels, widely loam covered, with a number of volcanic necks in the east.

**History.**—The earliest traceable signs of man in the region belong to the Paleolithic Age (Dragon's Cave, near Mixnitz). In the Neolithic and Bronze ages human occupation spread over the lower part of the country, and some mining was done in the mountains. The country was eventually included in the Celtic kingdom of Noricum (*q.v.*), which was incorporated into the Roman Empire c. 15 B.C. After the collapse of Roman rule in the 5th century A.D., Germanic peoples overran the country, and

in the 6th century it fell to the Avars (*q.v.*) and to their Slav subjects (Slovenes). After the breakup of the Avar dominion, the Slavs in the latter part of the 8th century were subjected by the Bavarians (*see* BAVARIA). With Bavaria, the country became part of the Frankish Empire. German colonization was intensified from 955 onward, and by c. 1300 Upper Steiermark was germanized. The southern countryside, however, remained predominantly Slav for several centuries.

The future Steiermark constituted the eastern part of the territory, which in 976 was detached from Bavaria to form the separate duchy of Carinthia (*q.v.*). Several of its northern countships, however, came in the 11th–12th centuries into the hands of the counts or margraves of the Traungau, whose main seat was at Styrburg, the modern Steyr (now in Oberösterreich); and in 1180 the whole area under this family was raised to the rank of a duchy (Steiermark or Styria) for Ottokar, the last member of the line. On his death the new duchy passed, in 1192, to the Babenberg duke of Austria, Leopold V (*see* BABENBERG). When the Babenberg family died out (1246), Steiermark was annexed by Bela IV of Hungary, but he had to cede the Traungau to Austria in 1254 and the rest of Steiermark to Otakar II of Bohemia in 1260. Otakar II in 1276 ceded his part of the country to the German King Rudolf I of the House of Habsburg (*q.v.*); and Rudolf in 1282 granted Austria (with the Traungau) and Steiermark jointly to his sons Albert I (the future German king) and Rudolf II. Thenceforward the history of Steiermark was merged with that of Austria (*see* AUSTRIA, EMPIRE OF), though from 1379 to 1439 and again from 1564 to 1619 it was not ruled directly by the senior branch of the House of Habsburg. The districts of Murau and Neumarkt (both west of Graz) and Cilli (Celje) were added to the duchy in the 15th century.

After World War I Austria in 1919 had to cede 2,329 sq.mi. (6,033 sq.km.) of southern Steiermark, including the towns of Marburg (Maribor), Cilli, and Pettau (Ptuj) to the new Kingdom of the Serbs, Croats, and Slovenes (later Yugoslavia). The rest of the country became a *Bundesland* of the Republic of Austria. On the *Anschluss*, or union of Austria and Germany (1938), Steiermark, apart from the Aussee district in the northwest but with the addition of the southern Burgenland, was constituted as a *Gau* (district) of the German *Reich*; and in 1941, during World War II, the territory lost in 1919 was restored to it. The boundaries of 1919 were reinstituted in 1945, when Steiermark again became a *Bundesland* of Austria.

**Population and Government.**—At the 1961 census the population was 1,137,865, with an overall density of just under 180 per sq.mi. (69 per sq.km.). Ethnically Steiermark is entirely German. The Slav heritage is represented only in place-names. About 90% of the inhabitants are Roman Catholic (included in the diocese of Seckau), and 6% are Protestant. The principal urban centres are: Graz (*q.v.*) (237,080), the capital and second town of Austria, Leoben (36,257), Kapfenberg (23,859), Bruck an der Mur (16,087), Knittelfeld (14,259), Eisenerz (12,435), Köflach (12,367), Mürzzuschlag (11,586), and Fohnsdorf (11,517). In the mountainous areas much ancient folklore, song, and dance are genuinely alive. The gray-green Steiermark suit is almost an Austrian national costume.

The *Bundesland* government consists of a governor and 8 members elected by, and responsible to, the provincial diet (*Landtag*), which has 56 members elected for five years by popular vote. The *Landtag* is a legislative body, but the acts it passes must be approved by the federal government. In the *Bundesrat* (federal upper house) Steiermark has seven votes. Administratively it is divided into 18 districts, including the city of Graz. Local government is in the hands of burgomasters and town and commune councils, which are elected for a five-year period.

**The Economy.**—Agriculture, which employs more than 40% of the working population, is important.

Steiermark's extractive industries are of prime importance. Most of Austria's iron ore is mined in the Erzberg. Brown coal is mined mainly at Fohnsdorf and Köflach, and magnesite in the Shale Alps. There is also a sizable production of graphite, talcum, gypsum, and common salt.

Heavy industry is concentrated in the Mur Valley below Fohnsdorf and in the Mürz Valley. Machine industries (including the production of motorcycles and railway rolling stock) and chemical, textile, leather, and food industries have been developed chiefly at Graz. Sawmills are numerous; the paper and cellulose industry is located largely in the Mur Valley between Leoben and Graz. Steiermark is self sufficient in electricity, which is generated in thermoelectric stations based on brown coal, as well as from waterpower derived from the Mur and other rivers.

**Communications.**—The most important routeway during the Middle Ages was the road from Italy via the Neumarkter Sattel (2,913 ft. [888 m.]), the westernmost crossing of the Central Alps below 3,281 ft. (1,000 m.), and then via the Semmering to Vienna. The main roads and railways followed the early routes. The Autobahn-Süd (projected) runs from Vienna through Steiermark to the Italian border via Graz and Klagenfurt. (K. A. S.)

**STEIN, SIR (MARK) AUREL** (1862–1943), Hungarian-British archaeologist, whose researches in central Asia revealed many aspects of that strategic region between eastern and western civilization, was born at Budapest, Hung., on Nov. 26, 1862, and became a British citizen in 1904. He was educated in Budapest and Dresden and at the universities of Vienna, Leipzig, and Tübingen; in Oxford and London (1884–87). Sir Henry Rawlinson influenced his studies in Oriental and classical archaeology and languages. In 1888 Stein went to India as principal of the Oriental College, Lahore, and registrar of the Punjab University. His friendship there with the Erasmian scholar P. S. Allen and Orientalist T. W. Arnold encouraged him in his geographical and archaeological research. In 1900 Stein published the *Chronicle of the Kings of Kashmir* and set out on the first of his central Asian expeditions, traveling to Khotan, north of the Kunlun Mountains. He went on four such expeditions between 1900 and 1930, tracing the caravan routes between China and the west and discovering the Cave of the Thousand Buddhas near Tun Huang.

As superintendent of the Indian Archaeological Survey (1910–29) Stein was interested especially in Greco-Buddhist remains and in tracing Alexander the Great's eastern campaigns; in 1925 he identified the site of Aornos at Pir-sar on the Indus River. He also investigated tells (ancient mounds) in Iran and Baluchistan to elucidate the relationships between the Mesopotamian and Indus civilizations. When political difficulties impeded work in Asia, Stein carried out two seasons of air photographic reconnaissance of the Roman frontier in Iraq (reported in the *Geographical Journal*, 1940). Stein had been created knight commander of the Indian Empire in 1912. He died at Kabul, Afg., on Oct. 26, 1943. His works include: *Ancient Khotan* (1907); *Serindia*, five volumes (1921); *Innermost Asia*, four volumes (1928); *On Alexander's Track to the Indus* (1929); *On Old Routes of Western Iran* (1940).

*See* C. M. Daugherty, *The Great Archaeologists* (1962). (J. M. W.)

**STEIN, CHARLOTTE VON** (1742–1827), famous for her intimate friendship with Goethe (*q.v.*), was born at Weimar on Dec. 25, 1742, the eldest daughter of the *Hofmarschall* (master of ceremonies). When she was 15 she became lady-in-waiting to Duchess Anna Amalia, the mother of Karl August, the duke of Saxe-Weimar. In 1764 she married Freiherr Friedrich von Stein, master of the horse to the duke; they had seven children. Goethe, who moved to Weimar in 1775, was captivated by her and for more than ten years she was his constant companion and the inspiration of much of his poetry. On Goethe's return from Italy in 1788 this close relationship between them came to an end although their friendship was later renewed. Goethe's letters to Frau von Stein form one of the most interesting sections of his correspondence. She was also a friend of Schiller and his wife. Her husband died in 1793 and she continued to live at Weimar, where she died on Jan. 6, 1827.

**BIBLIOGRAPHY.**—Goethe's *Briefe an Frau von Stein aus den Jahren 1776–1820* was ed. by A. Schöll, 3 vol. (1848–51), 3rd ed. by J. Wahl (1899–1900); and also by J. Petersen (1923) and H. H. Borcherdt (2nd ed. 1934). *See also* W. Bode, *Charlotte von Stein* (1910); L. Voos, *Goethes unsterbliche Freundin Charlotte von Stein* (1921); A. Nobel

**STEIN, GERTRUDE** (1874–1946), expatriate U.S. author and one of the more colourful personalities of the post-World War I literary scene, was born in Allegheny, Pa., Feb. 3, 1874. She spent her infancy in Vienna and Paris and her girlhood in Oakland, Calif. At Radcliffe College, where she was a student from 1893 to 1897, she studied psychology under William James, and then attended Johns Hopkins Medical School from 1897 to 1902. Of independent means, she went abroad to live in 1903. For more than a generation her home in Paris at 27 rue de Fleurus was a centre for artists and writers. She was, in the words of one of her protégés, Bravig Ihms, a "vital, headstrong and cordial personality," with "an insatiable appetite for people." They came and went in an unending procession, year after year, some famous, some unknown, some to become famous later: Henri Matisse, Pablo Picasso, Juan Gris, Clive Bell, Wyndham Lewis, Carl Van Vechten, Sherwood Anderson, Ezra Pound, Ford Madox Ford, Ernest Hemingway, André Gide, John Reed, Elliot Paul, Jo Davidson, Paul Robeson, and scores of others.

CULVER PICTURES

GERTRUDE STEIN, PHOTOGRAPHED IN 1942

Despite her German-Jewish origin, Miss Stein continued living in Paris during World War II under Nazi occupation. She died in Paris July 27, 1946.

A literary "cubist," Gertrude Stein carried to extremes her weird, repetitious and seemingly nonsensical manipulation of words, one of her celebrated phrases being "Rose is a rose is a rose." "Widely ridiculed and seldom enjoyed," comments Edmund Wilson in a chapter about her in *Axel's Castle*, "she has yet played an important role in connection with other writers who have become popular." In *The Autobiography of Alice B. Toklas* (1933), Miss Stein, while ostensibly writing the life of her secretary and close companion since 1907, actually wrote her own. Alice Toklas, so the autobiography recounts, knew personally three geniuses in her lifetime: Picasso, Alfred North Whitehead, and Gertrude Stein.

Among Miss Stein's works are: *Three Lives* (1908); *Tender Buttons* (1915); *The Making of Americans* (1925); *Useful Knowledge* (1928); *Ten Portraits* (1930); *Lucy Church Amiably* (1930); *Before the Flowers of Friendship Faded Friendship Faded* (1931); *How to Write* (1931); *Operas and Plays* (1932); *Matisse, Picasso and Gertrude Stein* (1932); *Four Saints in Three Acts*, an opera libretto (1934); *Lectures in America* (1935); *Narration* (1936); *Picasso* (1938); *Ida* (1941); *Brewsie and Willie* (1946). Carl Van Vechten edited her *Last Operas and Plays* (1949).

**BIBLIOGRAPHY.**—D. Sutherland, *Gertrude Stein: a Biography of Her Work* (1951); H. R. Garvin, *Gertrude Stein: a Study of Her Theory and Practice* (1950); E. Sprigge, *Gertrude Stein: Her Life and Work* (1957).

**STEIN, KARL, FREIHERR VOM UND ZUM** (1757–1831), German statesman in the Prussian service, the sponsor of far-reaching reforms during the Napoleonic Wars, and a major benefactor of historical research. He was born at Nassau on Oct. 26, 1757, into a family of the knightly class, the son of a chamberlain in the service of the elector of Mainz. His ancestral tradition, as he himself declared, imbued him with "ideas of piety, patriotism, class and family honour, and the duty of devoting one's life to the community's needs and of acquiring the necessary proficiency for such purposes by diligence and effort." He grew up to feel a strong attachment to the old German *Reich* and to the imperial dynasty of the Habsburgs and a fervent German patriotism.

At the age of 16 Stein went to the school of law and political

science at the University of Göttingen. From his reading there in early German history, in English literature and constitutional theory, and in the works of Montesquieu, he received impressions that were to be of significance for his later activity as a statesman. He then completed his training with experience in the institutional organs of the *Reich*, namely the Imperial Chamber at Wetzlar, the Imperial Court Council in Vienna, and the *Reichstag*, or Diet, of the empire at Regensburg. In 1780, however, he entered the Prussian government service.

#### Service in Westphalia and the Ministry of 1804–07.—

Work in the direction of mining enterprises and in the provincial administration of Prussian Westphalia made Stein an expert in the practical detail of local government. In 1796 he was appointed head of all the Rhenish and Westphalian administrative districts; and in 1802–03 he was entrusted with the administrative execution of the merging of the secularized bishoprics of Münster and Paderborn into the Prussian state. On Oct. 27, 1804, he was summoned to Berlin to be minister for manufactures and excise; i.e., for economic affairs. In this capacity he obtained an insight into the working of the central offices of the government, which moreover convinced him of the need for reform. Because of a momentary altercation with King Frederick William III (*q.v.*), who rejected his demands for a ministerial system free of interference from the king's personal cabinet, Stein was dismissed from office on Jan. 3, 1807, in the interval between the defeat of the Prussians by the French at Jena and Auerstädt (October 1806) and the Peace of Tilsit (July 1807; see NAPOLEONIC WARS).

**The Nassau Memorandum.**—Returning to his paternal house, Stein used his enforced leisure to compose, in April–June 1807, the so-called Nassau Memorandum (*Nassauer Denkschrift*). A comprehensive program for the reform of the Prussian state, this memorandum constitutes the best and most reliable account of Stein's ideas. His basic principle is that, for a healthy and efficient state, an organic relationship must be established between population and government and that citizens must be brought into responsible participation in the state's affairs. This view had long been developed, formulated, and modified in his mind through his preoccupation with the English system of self-government and through his objections to the theories of Montesquieu, of the Physiocratic School, and of the French Revolution; and experience had enriched and reinforced it. Seeking to give new life to the state from within, he hoped that the practice of self-government would generate "civic-mindedness" (*Bürger-sinn*) and "community spirit" (*Gemeingeist*) in them, so that they would make its interests their own: a revived enthusiasm for "fatherland, independence, and national honour" should turn sources of energy, hitherto neglected or misapplied, into channels of positive activity.

**The Ministry of 1807–08.**—Under the Peace of Tilsit, which mutilated the Prussian state, Frederick William III had to dismiss his minister K. A. von Hardenberg (*q.v.*) at Napoleon's behest. He then invited Stein to be his chief minister, on Napoleon's recommendation. Stein arrived at Memel on Sept. 30, 1807, and after interviews with the king his new appointment was confirmed (Oct. 4). Confronted with the extraordinary situation of Prussia, the single-minded, uncompromising, and self-confident Stein saw the opportunity for fundamental reform. The old system of the state was quite obviously discredited; even the otherwise irrevocable king could see that it was high time to put Prussia on a more up-to-date footing. Furthermore, Napoleon's demands on Prussia themselves necessitated incisive measures affecting the internal system. Last but not least, some of the liberally inclined members of the bureaucracy, inspired partly by Adam Smith, partly by Immanuel Kant, and partly by French Revolutionary ideas, were ready to collaborate with Stein.

Thus, from the earliest days of his tenure of office, Stein could launch his reform. On Oct. 9, 1807, a law was published "concerning the Emancipated Possession and the Free Use of Landed Property as well as the Personal Relationships of the Inhabitants," which freed the peasants from servitude. Though it did not furnish a satisfactory solution to a number of problems (foremost among them being that of the gradual transfer of

economically exploited land to peasant ownership), this October Edict was a decisive step in the conversion of Prussia to civil liberty and to equality before the law. No less revolutionary were the economic implications: land, which nobles had been forbidden to sell to nonnobles, could henceforth be bought and sold freely, and men were free to follow the vocation of their own choosing.

Stein's Municipal Ordinance (*Städteordnung*) of Nov. 19, 1808, was of lasting importance. It introduced self-government for the urban communes, created the distinction between the salaried executive officials (mayor and magistrate) and the town councils, and so enabled the towns to deal with their local affairs largely through their own citizenry. Even so, the greater towns were put under the supervision of a police president directly responsible to the minister of the interior. Stein's ordinance pointed the way to the development of municipal life throughout Germany.

Stein effectively modernized the structure of the Prussian government as a whole. The irresponsible advisers of the absolute king, namely the so-called cabinet councilors, who had hitherto formed a sort of secret government behind the scenes, were discarded; and so also was the "General Directory," which had been set up as the central authority in Frederick William I's reign (1713-40). In its place Stein established departmental ministries (foreign affairs, internal affairs, finance, justice, and war) with unified competence for the whole Prussian territory. On the same principle he organized the activities of the intermediate administrations or *Regierungen* and created the post of *Oberpräsident*, or official head of a whole province, directly responsible for it to the central government.

Stein pursued his many-sided tasks with passionate determination, but much of his plan remained unexecuted. His schemes for agrarian and economic reform were taken up by Hardenberg from 1810 onward; but the latter applied them in a spirit more akin to that of the Enlightenment than to Stein's conservative sort of liberalism and without Stein's educative, ethico-political concern.

**Exile, and the War of Liberation.**—In August 1808 a letter in which Stein indiscreetly referred to the likelihood of war against France was intercepted by Napoleon's agents; and on Nov. 24, yielding to French pressure, Frederick William dismissed him from office. Next, when Napoleon had declared him a public enemy (Dec. 16), Stein had to take refuge on Austrian territory. In May 1812 he was summoned to the court of the Russian emperor Alexander I (*q.v.*), to be one of his political advisers. In the following winter, on the collapse of Napoleon's invasion (*see* again NAPOLEONIC WARS), he urged the pursuit of the retreating French Army beyond the Russian frontiers; and early in 1813 he not only helped to organize the raising of troops in East Prussia but also negotiated the Russo-Prussian Treaty of Kalisz, the formal signal for Prussia's rising against Napoleon. He used his moral authority, during the War of Liberation and the Congress of Vienna, to work for a political union of the German states.

**Monumenta Germaniae Historica.**—In 1816 Stein retired to his country property of Kappenberg in Westphalia. Even in his old age his energy did not desert him. German historical science, in fact, owes to Stein's efforts its most important enterprise of publishing. The *Gesellschaft für ältere deutsche Geschichtskunde* ("Society for Earlier German History") was founded on Jan. 20, 1819, at his house in Frankfurt am Main, with him as its head and its coordinating force. Thus the publication of the great documentary series *Monumenta Germaniae Historica*, which began in 1826, became the particular occupation of Stein's last years. As he himself said, he called the *Monumenta* into being "in order to give life to the savour of German history, to facilitate the study of its foundations, and thereby to contribute to the preservation of love of the common fatherland."

**Conclusion.**—Respected as marshal of the provincial Diet of the Westphalian Estates (from 1826), and honoured both as a landowner and as a family man, Stein died on June 29, 1831. He

had been the greatest statesman concerned with Prussia's internal affairs since Frederick William I. His achievement consisted essentially in having so mitigated the authoritarian character of an absolute state as to introduce elements of liberalism and of constitutionalism. He had also been a political educator of the German people.

An edition of Stein's correspondence, memoranda, and notes, by E. Botzenhart, appeared in 1931-42, in eight volumes; a new edition of his letters and official writings, also by Botzenhart, began to appear in 1957. Other governmental and administrative documents of Stein's are edited by G. Winter, *Die Reorganisation des Preussischen Staates unter Stein und Hardenberg*, volume 1 (1931). There is an edition of Stein's autobiography by K. von Raumer (1955).

Ritter, *Stein, eine politische Biographie*, 2 vol. (1931; 3rd ed., 1 vol., 1958); F. Schnabel, *Freiherr vom Stein* (1931). Works in English are: Sir J. R. Seeley, *Life and Times of Stein* (1879); G. S. Ford, *Stein and the Era of Reform in Prussia, 1807-15* (1922); C. de Gruenwald, *Baron Stein, Enemy of Napoleon* (1936). (E. W. Z.)

**STEINBECK, JOHN ERNST** (1902- ), U.S. writer, who achieved fame in the 1930s for his powerful novels about agricultural workers in California and who received the Nobel Prize for Literature in 1962, was born in Salinas, Calif., on Feb. 27, 1902. He attended Stanford University intermittently between

ERICH HARTMANN—MAGNUM

JOHN STEINBECK, PHOTOGRAPHED IN 1962

1920 and 1926 but did not take a degree. His early novels, *Cup of Gold* (1929), *The Pastures of Heaven* (1932), and *To a God Unknown* (1933), were relatively unknown until *Tortilla Flat* (1935) brought him popularity. *In Dubious Battle* (1936) remains one of the best strike novels in the English language. *Of Mice and Men* (1937), a novella about the strange, complex bond between two migrant labourers, was adapted for the stage and received the Drama Critics Circle award. His Pulitzer Prize winning novel, *The Grapes of Wrath* (1939), about the migration of a dispossessed family from the Oklahoma dust bowl to California and their consequent exploitation by a ruthless system of agricultural economics, remains his best-known work. The furor

occasioned by this novel's realistic picture of migrant workers and what the public assumed to be its political and economic theories became a colourful national event.

During World War II Steinbeck wrote some effective pieces of propaganda, among them *The Moon Is Down* (1942) and *Bombs Away* (1942), and he also served as war correspondent for the *New York Herald Tribune*. His immediate postwar work—*Cannery Row* (1945), *The Pearl* (1945, 1947), *The Wayward Bus* (1947)—reflected a bitterness against the greedy, rapacious elements of society that had made the horrors of war possible. In *Burning Bright* (1950) and *East of Eden* (1952) Steinbeck turned away from the naturalistic preoccupations and techniques of the 1930s and asserted that all men are brothers, keepers of one another, and that each man has the power to choose between good and evil. His later books, including *Sweet Thursday* (1954), *The Short Reign of Pippin IV* (1957), *The Winter of Our Discontent* (1961), and *Travels With Charley* (1962), are comparatively slight works of entertainment and journalism, widely popular in their appeal.

Steinbeck's early reputation as a proletarian, naturalistic writer of sociological penetration, and his constant experimentation with materials and techniques, tended to obscure other facets of his

writing, but under subsequent scrutiny much of his work has revealed itself rich in symbolic structures and mythopoeic qualities.

**STEINER, JAKOB** (1796–1863), Swiss mathematician, one of the founders of modern synthetic geometry, was born at Utzenstorf, Bern, on March 18, 1796. He grew up without schooling; only at 14 did he learn to write. Against the wish of his parents, at 18 he went to the Pestalozzi school at Yverdon where his extraordinary geometric intuition was discovered. Later he went to Heidelberg and Berlin to study, supporting himself precariously as a tutor. The founding of August Crelle's *Journal* (1826) gave him an opportunity to publish his geometric discoveries. In 1832 he received an honorary doctorate from the University in Königsberg, and in 1834 was appointed extraordinary professor at the university in Berlin, a post he held until his death on April 1, 1863, in Bern (see **GEOMETRY**; *Projective Geometry*).

Steiner was one of the great developers of projective geometry, and many of the basic concepts and results in this field are due to him. His writings were collected as *Gesammelte Werke*, 2 vol. (1881–82).

See J. H. Graf, *Der Mathematiker Jakob Steiner* (1897); L. Kollros, *Jakob Steiner* (1947). (O. Oe.)

**STEINER, RUDOLF** (1861–1925), Austrian philosopher, scientist, and artist, who formulated the philosophic theory known as anthroposophy, was born on Feb. 27, 1861, at Kraljevic, Aus., the son of a railway stationmaster. After an education, supplemented by much self-education, completed at the Technische Hochschule in Vienna, he edited an edition of Goethe's scientific writings, and from 1889 to 1896 worked on the standard edition of Goethe's works at Weimar. During this period he wrote *Truth and Science*, which secured his Ph.D., and his best-known philosophical work, *Die Philosophie der Freiheit* (1894). He then moved to Berlin where he was successively editor of the *Magazin für Literatur* and lecturer in a workingmen's college. Meanwhile he was developing a faculty for spiritual perception independent of the senses. The result of these researches, which he called anthroposophy and described as "knowledge produced by the higher self in man," brought him in 1902 into connection with the Theosophical Society (see **THEOSOPHY**), but he found himself out of sympathy with its subsequent policy, and founded the independent Anthroposophical Society in 1912. Anthroposophy postulates the existence of a spiritual world comprehensible to pure thinking but fully accessible only to the higher faculties of knowledge latent in every man. Historically, Steiner regarded man as having originally participated in the spiritual processes of the world through a dreamlike consciousness out of which the more limited but awake consciousness of today has crystallized. He claimed that an enhanced consciousness can again achieve perception of spiritual worlds. In 1913 Steiner began to build the first *Goetheanum* at Dornach, near Basel, Switz., as a "school of spiritual science." This was burned in 1922, but Steiner immediately designed another, of molded concrete, which became the centre of the Anthroposophical Society. He died there on March 30, 1925.

Activities derived from Steiner's work include: the Waldorf School movement, by the late 1950s comprising some 60 schools and 25,000 children in Europe and America; homes and schools for defective and maladjusted children; a therapeutic movement with a central clinic at Arlesheim, Switz.; the biodynamic method of farming and gardening; centres for scientific and mathematical research; eurythmy, an art of movement to speech and music; and schools of drama, speech, painting, sculpture, and architecture. After World War I Steiner proposed a threefold organization of society as a solution of political, social, and economic questions.

**BIBLIOGRAPHY.**—Of Steiner's numerous published works, which included lecture courses on man's relation to the earth and the universe, eurythmy, education, spiritual science, architecture, economics, and studies in the Gospels and Genesis, the following are the most important. Dates and titles are of the latest English edition; the original date of publication is given in brackets. *The Philosophy of Spiritual Activity* (1949 [1894]); *Goethe's Conception of the World* (1928 [1897]);

*Theosophy* (1955 [1904]); *Occult Science: an Outline* (1950 [1913]); *Knowledge of the Higher Worlds and Its Attainment* (1932 [1909]); *The Threefold Commonwealth* (1920); *Story of My Life* (1924).

**STEINMETZ, CHARLES PROTEUS** (1865–1923), U.S. electrical engineer, one of the outstanding electrical geniuses of the United States, was born at Breslau, Ger., April 9, 1865. He was educated at Breslau, Zürich, and Berlin, specializing in mathematics, electrical engineering, and chemistry. His activities as a

THE GRANGER COLLECTION  
STEINMETZ

Socialist led him into difficulties with the authorities, and, after a short sojourn in other countries, he emigrated in 1889 to the United States and found work with the Osterheid and Eickemeyer factory at Yonkers, N.Y. In 1893 when that factory was absorbed by the General Electric Co., Schenectady, N.Y., he was given an appointment as consulting engineer. His knowledge won him speedy promotion. After 1902 he served also as professor of electrical engineering at Union College, Schenectady, N.Y. Steinmetz regarded his three greatest contributions to electrical science to be: (1) his investigations on magnetism, resulting in his discovery of the law of hysteresis, which enabled losses of electric power due to magnetism to be accurately forecast before starting the construction of motors, generators, transformers, and other electrical apparatus employing iron; (2) the development of his symbolic method of calculating alternating-current phenomena, which simplified an extremely complicated field, understood by few, so that the average engineer could work with alternating current, an accomplishment which was largely responsible for the rapid progress made in the commercial introduction of alternating-current apparatus; (3) his investigation of lightning phenomena, which resulted in his theory of traveling waves and opened the way for his development of lightning arresters to protect high-power transmission lines. Though primarily a mathematical genius and a student of theory, Steinmetz had about 200 patents to his credit, including improvements on generators, motors, transformers, in electrochemical operations, and the invention of the induction regulator, the method of phase transformation, and the metallic electrode arc lamp. He was the author of a number of standard textbooks, in addition to a large number of scientific papers.

Steinmetz died at Schenectady, N.Y., Oct. 26, 1923.

**STELLENBOSCH**, a town of Cape of Good Hope Province, Republic of South Africa, lies beside the Eerste River, 31 mi. (50 km.) E of Cape Town. Pop. (1960) 22,333, of whom 10,738 are white. Stellenbosch is attractively laid out: it has a number of stately houses dating from the 17th and 18th centuries, its streets are lined with oak trees, and there are numerous gardens and parks. It is generally regarded as one of the major centres of Afrikaans culture and learning, and among its educational institutions are the University of Stellenbosch, a training college, a theological seminary, research laboratories, and many schools. Stellenbosch is in the centre of a fertile farming area, and its chief industries are wine making, fruit production, and sawmilling. After Cape Town it is the oldest town in South Africa, founded in 1679 and named after the Dutch governor of the Cape, Simon van der Stel. (V. C. R. D.)

**STEM**, along with the root and leaf, is a characteristic vegetative organ of vascular plants (Tracheophyta; *q.v.*). Popularly, the stem is the stalk of a plant or the secondary limb of a tree;

botanically, it is the plant axis that bears the leaves. The stem conducts water, minerals, and food through vessels (xylem and phloem) and often serves as an organ of storage; green stems, like the green leaves they support, manufacture food for the plant (see PHOTOSYNTHESIS).

In most plants the stem is an obvious and dominant aerial shoot, but in some it may be considerably modified, resembling other plant parts. Plants with a distinct stem are caulescent; those with an inconspicuous or buried stem are acaulescent, as the primrose, cowslip, and dandelion.

**General Features.**—Many underground stems resemble roots, but they can always be distinguished by their terminal bud and evidences of leaf attachment (leaf scars) and by the absence of a protective cap for the growing tip (the rootcap of roots). Internally, the bundles or bands of vascular tissue are peripheral or scattered, never central or radial, as in the root. The relationship of the xylem and phloem is also diagnostic for stems (see PLANTS AND PLANT SCIENCE: *Vascular System*).

**Development.**—The first rudiment of the young shoot of the embryo appears from the seed after the radicle (young root) has protruded. It is termed the plumule and differs from the radicle in the absence of a rootcap and in its tendency to ascend (see SEED). The apical growing portion constitutes the terminal bud of the plant, and by continued development the stem increases in height; projections appear at intervals, which are the rudimentary leaves. Lateral buds are produced that develop into lateral shoots more or less resembling the parent stem, and by these the branching of the plant is determined. A bud may be found in the axil of a previously formed leaf or, in other words, in the angle formed between the stem and leaf. Such buds are called axillary and are produced like the leaves from the tissues of the stem. During their development vascular bundles are formed that are continuous with those of the stem. Ultimately branches are produced that in every respect resemble the axis from which the bud was differentiated. The place of origin of the leaf is called a node; the intervals between nodes are called internodes.

**Functions of the Stem.**—The primary functions of the stem are support of the leaves, conduction of water and nutrient substances to the leaves, and movement of elaborated foods from them. Other functions which may be performed by stems are storage of reserve food, photosynthesis, and vegetative reproduction. The regular arrangement of leaves on the stem distributes them in such a manner that they are equally exposed to the light, as is necessary for photosynthesis (see LEAF: *Arrangement or Phyllotaxy*). The stem also supports the flowers.

FIG. 2.—MICROSCOPIC STRUCTURE OF A SUNFLOWER STEM

Conduction of water and nutrient salts from regions of absorption in the roots to the leaves takes place through certain vas-

cular elements of the xylem (vessels and tracheids), while the movement of synthesized foods from the leaves to other organs of the plant occurs chiefly through the phloem (see PLANTS AND PLANT SCIENCE: *Translocation of Water and Translocation of Solutes*). Radial movement of food within the stem may take place through ray and other parenchymatous cells. Storage of food and water frequently occurs in stems. Examples of food-storing stems are specialized forms, such as tubers, corns and rhizomes, and the woody stems of trees and shrubs. Water storage in stems is developed to a high degree in cacti.

All green stems carry on some of the photosynthetic work of the plant, but in most cacti this function is performed chiefly by the stem, the leaves being present often only for brief periods or as spines. Other plants in which food making is carried on in large measure by the stem are asparagus and various species of euphorbias. When the stem is specialized so that it is flattened and leaflike, it is termed a cladophyll, as in butcher's-broom or asparagus. Vegetative reproduction is accomplished by aerial stems like the stolons, or runners, of strawberries and by underground stems among the grasses and many members of the lily family.

**Growth and Bud Formation.**—Growth in length of the stem results from the activity of the apical meristem and elongation of the internodes. The zone of most rapid growth is at some distance below the apex; below this, the rate of growth gradually diminishes until the part is reached where growth in length no longer takes place. In some stems, as in those of grasses, growth in length persists for a longer time in a small region at the base of the internodes; this is known as intercalary growth. In shoots of limited growth, such as those of the larch, the internodes elongate only slightly and the leaves remain close together. Lateral buds give rise to branches, from which others, called branchlets or twigs, arise. The terminal bud sometimes dies at the end of one season, and the whole plant, as in annuals, perishes; or part of the axis is persistent and remains for two or more years, each of the leaves before its decay producing a bud in its axil, which continues the growth in the spring.

In ordinary trees, in which numerous lateral buds are formed, any injury done to a few branches is easily repaired; but in palms, which form mainly terminal buds and have no other provision for a lateral formation of them, destruction of the terminal bud results in no further growth of the tree. In the trees of temperate and cold climates the buds, which are developed during one season, lie dormant during the winter, ready to open in the spring. They are generally protected by specialized leaves in the form of scales, which frequently exhibit a firmer and coarser texture than the foliage leaves. They serve a temporary purpose and usually fall off sooner or later after the leaves are expanded. The bud is often protected by a coating of resinous matter, as in the horse chestnut and balsam poplar, or by a thick downy covering, as in the willow.

In plants of warm climates the buds are often devoid of any protecting appendages; such buds are called naked.

When the terminal bud is injured or arrested in its growth, the elongation of the main axis stops, and the lateral branches often acquire increased activity. By continually cutting off the terminal buds or branches, a woody plant is made to assume a bushy appearance, and thus pollard trees are produced. The peculiar bird's nest appearance often presented by the branches of the common birch depends on an arrestment in the terminal buds, shortening of the internodes, and a consequent clustering of the twigs.

**Types of Stems.—Growth Habit.**—The character of the stem may be related to the longevity of the plant. Thus many herbaceous plants or herbs are annuals and complete their life cycle in one growing season, after which the entire plant dies. In biennial herbs the whole plant dies after two years; the lower part of the stem or crown persists after the first growing season and bears buds from which an erect stem arises the second season. In perennial herbs the short crown stem may produce new shoots for many years. Plants producing permanent woody stems are called trees and shrubs. The latter produce branches from or near the

FROM H. J. FULLER AND O. TIPPO, "COLLEGE BOTANY"; HOLY, RINEHART AND WINSTON  
FIG. 3.—DIAGRAMS OF LONGITUDINAL SECTION (CENTRE) OF A STEM TIP AND CROSS SECTIONS TAKEN AT DIFFERENT LEVELS AS INDICATED BY DOTTED LINES

ground, while the former have conspicuous trunks. Shrubby plants of small stature are called undershrubs or bushes. The limits between these different kinds of stems are not always well defined; and there are some plants occupying an intermediate position between shrubs and trees, sometimes called arborescent shrubs (see TREE). In general, the habit of the stem is erect or ascending, but it may lie prostrate on the ground, thus becoming procumbent, as in the sweet potato and strawberry. The scandent stem may climb on rocks or plants by means of rootlets, as in ivy; other vines have twining stems that twist around a supporting plant in a spiral manner, as in morning-glory, dodder, honeysuckle, and hop. In other cases, climbing plants are supported by tendrils, which may be specialized stems, as in the grape and passionflower. In warm climates twining plants often form thick woody stems and are called lianas, while in temperate regions they are generally herbaceous vines (*q.v.*).

In some plants the stem does not elongate during its early development but forms a short conical structure from which a crown of leaves arises. These may form a bulb (onion, lily), a head (cabbage, lettuce), or a rosette (dandelion, plantain). Later this type of stem may grow rapidly into an elongated axis. Subterranean stems include rhizomes, corms, and tubers.

**Rhizome.**—A rhizome or rootstock is a horizontal stem usually sending out numerous adventitious roots and leaf buds from its upper surface. It occurs in ferns, the iris, *Acorus* or sweet flag, ginger, the water lily, many species of *Carex*, rushes, grasses, anemone, etc. The leaves develop as scales. By the presence of leaf-scales and a bud at the apex, and by the absence of a root cap, a rhizome can be distinguished from a root.

A rhizome such as in Solomon's seal is not the product of a single bud but is composed of portions of successive axes, the aerial parts of which have died off, leaving scars. A rhizome sometimes assumes an erect form, as in *Scabiosa succisa*, in which the so-called praemorse root is in reality a rhizome, with the lower end decaying. The erect rhizome of water hemlock (*Cicuta virosa*) has hollow internodes, separated by partitions. In the coralroot orchid (*Coralorhiza*), which grows in soil rich in humus, no roots are developed,

the corallike branching rhizome acting as the absorbing organ.

**Tuber.**—A tuber is a short thickened stem or branch in which there is little internodal elongation, as in the potato. The eyes of the potato are leaf buds. Tubers are sometimes aerial, occupying the place of branches. The ordinary herbaceous stem of the potato, when cut into slips and planted, sends off branches from its base, which assume the form of tubers.

Tubers frequently store up a quantity of starch, as in *Maranta arundinacea*, from which West Indian arrowroot is derived.

**Corm.**—Another form of thickened underground stem is the corm, as seen in the autumn crocus (*Colchicum*), gladiolus, etc. Structurally it is composed of a solid, more or less rounded axis covered by thin membranous scales.

A corm often persists for only one year, giving off buds annually in the form of young corms. In the axil of an upper leaf of one (or more) of the bud corms the flowering stem develops and bears the flowers. The flowering stem dies down and the bud corm, from which it arose, enlarges greatly at the expense of its parent corm, which thus becomes shriveled. In spring the corm that flowered the spring before sends out large leaves, which were mere rudiments the previous autumn. At the end of spring these leaves die down; only the bases of the lower ones remain as thin brown scales around the corm.

This corm, in its turn produces in the axils of its leaves new bud corms, which form rudimentary leaves in the autumn. The following spring one (or more) of these bud corms produces the flowering stem and, eventually, leaves and new bud corms; and thus the cycle goes on.

**Bulb.**—The bulb is a bud that is often subterranean. The axis in this case is much shortened, and the internodes are unelongated. The bases of the leaves rising from the stem are close together and become succulent and enclose the axis. In the lily the thick and narrow scales are arranged separately in rows, and the bulb is called scaly; while in the leek, onion, and tulip the scales are broad and enclose one another in a concentric manner, the outer ones being thin and membranous, forming a covering. In the axils of these fleshy scales new lateral shoots arise, forming new bulbs.

The lateral buds may remain attached to the axis and produce flowering stems, so that apparently the same bulb continues to flower for many years, as in the hyacinth and tulip; in other species the young bulbs form separate plants.

In the axil of the leaves of *Lilium bulbiferum*, *Dentaria bulbifera*, and some other plants, small conical or rounded bodies are produced, called bulbils or bulblets. They resemble bulbs and consist of a small number of thickened scales enclosing a growing point. These scales are frequently united closely together, so as to form a solid mass. The scales in bulbs vary in number. In *Gagea* there is only one scale; in the tulip and crown imperial they vary from two to five; while in lilies and hyacinths there are a great number of them.

JOHN H. GERARD

(LEFT) CORM OF A GLADIOLUS; (CENTRE) BULB OF A MADONNA LILY; BOTH IN VERTICAL SECTION. (ABOVE) RHIZOME OF AN IRIS

**Other Modifications.**—Branches are sometimes long and slender and run along the ground, producing buds and adventitious roots at their extremity. This is seen in the runner of the strawberry. In the houseleek (*Sempervivum tectorum*) there is a similar prostrate branch of a shorter and thicker nature, known as an offset, producing a bud at its extremity capable of independent existence. In many instances the stem decays, and the young plant is separated from the parent plant.

Gardeners propagate plants by the process of layering, which consists in bending a twig, fixing the central part of it into the ground and, after the production of roots, cutting off its connection with the parent. A stolon is a stem that curves toward the ground and, on reaching a moist spot, takes root and forms an upright stem and ultimately a separate plant. This is a sort of natural layering, and the plant producing such branches is called stoloniferous. In the rose and mint a subterranean branch arises from the stem, which runs horizontally to a certain extent and ultimately sends up an aerial stem, which may become an independent plant. Such branches are denominated rhizomes or suckers, and the gardener cuts the connection between the sucker and the parent stem to propagate these plants.

In asparagus and other plants that have a perennial stem below ground, subterranean buds are annually produced that appear above ground as shoots or branches covered with scales at first, and ultimately with cladophylls resembling true leaves. These branches are herbaceous and perish annually, while the main stem remains below ground to send up fresh shoots the following season.

In bananas the aerial stem is a shoot sent up by an underground stem and perishes after fruiting. Branches are sometimes arrested in their development and, in place of forming leaves, develop as spines or thorns, as in the hawthorn. Plants that have spines in a wild state, as the apple and pear, often are less spiny when cultivated; in some cases, as in the fire thorn (*Pyracantha*

(H. E. Hd.; K. E.; X.)

**STENDAL**, a town of East Germany in the *Bezirk* (district) of Magdeburg, German Democratic Republic, 70 mi. (113 km.) W of Berlin on the Uchte River. Pop. (1964) 35,931. It is a railway junction on the Hanover-Berlin line. There are many churches and gates in Gothic style, built in brick; the town hall is an imposing complex of buildings in Gothic and Renaissance styles. There are two parks, a zoological garden, and a museum. In front of the town hall is a 16th-century Roland's column, a symbol of municipal freedom. Stendal's industries include chemicals, metal goods, preserves, and sugar refining.

The town was once the capital of the Altmark. The first settlers were the Lower Saxons, the Wends, the Netherlanders, and the Rhinelanders. It was first mentioned in a charter of 1022 and was given municipal rights between 1150 and 1170 by Albert I, the Bear. As a member of the Hanseatic League, it rose to the height of its prosperity from the 13th to the 15th century by the weaving and trading of cloth. The archaeologist J. J. Winckelmann (1717-68) was born there. (A. Sz.)

**STENDHAL** (pseudonym of MARIE HENRI BEYLE) (1782-1842), one of the greatest French novelists, and the author of many original and entertaining works.

**Life.**—The elder child of a Chérubin Beyle and Henriette (née Gagnon), he was born on Jan. 23, 1783, at Grenoble, where he spent his first 16 years, of which he has left a vivid account in *La Vie de Henri Brulard*. He was devoted to his mother, who died when he was seven, but was always on bad terms with his father, whom he nicknamed "the bastard," and whom he suspected unjustly, of deliberately keeping him short of money. His bitterness increased when he learned on his father's death in 1819 that, owing to business misfortunes, he would not inherit the fortune that he had confidently expected. Stendhal detested Grenoble—which he called "mudhole"—and its middle-class society with their monarchist sympathies. "My family," he wrote, "were the most aristocratic people in the town, which meant that I became a fanatical republican on the spot." He added that though he would do anything in his power "to ensure the happiness of the common people," he would prefer "to spend a fortnight of every month in prison rather than have to live with tradesmen." He claimed to be of Italian descent on his mother's side. This was long thought to be a characteristic piece of fantasy, but research suggests that there may be something in it. Stendhal used it as an explanation of his curiously contradictory nature. He was a mathematician and an adventurer, equally enthusiastic over the *logique* of the philosophers and what he called *espagnolisme* (the passionate ebullience typified for him by his maternal great-aunt).

At the École Centrale at Grenoble (1796-99), he was a brilliant

FROM W. W. ROBBINS AND T. E. WEIER, "BOTANY, AN INTRODUCTION TO PLANT SCIENCE," JOHN WILEY & SONS, INC.

FIG. 4.—STEM MODIFICATIONS

pupil. He then went to Paris, ostensibly to study at the École Polytechnique, but in reality to escape from Grenoble. Although the heroes of two of his novels went to the Polytechnique, he himself found the entrance examination too much trouble and soon abandoned the idea. He fell ill and was befriended by his cousins, the Darus. Pierre Daru was a high official at the Ministère de la Guerre, where he obtained a clerkship for Stendhal. Later in 1799 Stendhal was posted to Milan during Napoleon's second Italian campaign. While he was there Daru secured him a commission in the 6th Dragoons.

BY COURTESY OF THE MUSÉE STENDHAL, GRENOBLE; PHOTO, STUDIO PICARDY

STENDHAL: PORTRAIT BY P. J. DEDREUX-DORCY

His enthusiasm for military life is famous, but in practice he found the army boring and disappointing. He soon became an expert in all the tricks of the "old sweat." His biographers have disproved the large claims made for him in army reports as a soldier, showing that he was never a combatant. He returned to France in 1802 and resigned his commission.

He had gone to Paris in the hope of achieving fame as a writer and happiness through love. Neither hope met with immediate success. Although he planned his conquests with the care of an 18th-century roué, he was a timid and bungling seducer who was rebuffed by most of his intended victims, including Mme Daru, his protector's wife. He announced, blithely and publicly, that he intended to become a "comic bard" and Molière's successor. He went assiduously to the theatre, attended a dramatic school, and hammered away intermittently for nearly 40 years at his plays. He complained of the difficulty of writing Alexandrines, but his genius was for prose fiction, not verse drama.

He became infatuated with an actress, Mélanie Guilbert, and in 1805 followed her to Marseilles, where for a few months he was a wholesale grocer. When the business failed, he returned to the Ministère as deputy to the *commissaire des guerres*. He spent two years (1806-08) with the army in Brunswick, applied unsuccessfully for a post in Spain, and took part, on the quartermaster's staff, in Napoleon's Russian campaign of 1812. He had a close view of the horrors of war in Russia and described them in some of his most brilliant letters. When the empire fell, he was angling for a prefecture. Seeing no prospect of employment under the new regime, he spent the years 1814-21 in Italy, six of them mostly at Milan, the home of Angela Pietragrua, who became his mistress in 1811, ten years after their first meeting, and provided him with material for several of his heroines.

In 1821 the Austrian police, who suspected him of espionage, asked him to leave Milan. This was a heavy blow. Italy was the land of his dreams; his love of it gives his novel *La Chartreuse de Parme* its youthfulness and spontaneity. He spent most of the next nine years in Paris, where he became a familiar figure in literary circles. He met Destutt de Tracy (*q.v.*), whose philosophy he greatly admired, and made friends with Prosper Mérimée. He also published his first two novels, *Armance* (1827) and *Le Rouge et le noir* (1830). In 1821 and 1826 he visited England and wrote engagingly of his visits in *Souvenirs d'égotisme* (1892).

Shortly after the July Revolution of 1830 he was appointed consul at Trieste, but Metternich refused him his exequatur, and he was sent instead to Civitavecchia in April 1831. It was not an exciting post but left him ample time for writing. While there, he wrote the romanticized autobiography *Henri Brulard* (1890), the novel *Lucien Leuwen* (1894), and part of the novel *Lamiel* (1889), all unfinished and posthumously published. In his later years, afflicted with boredom and poor health, he managed to wangle long leaves in Paris. During one of them, in the autumn of 1838, he wrote his masterpiece, *La Chartreuse de Parme* (1839), in only seven weeks.

He returned to France on sick leave in November 1841. On March 22, 1842, he attended a large official reception given by François Guizot at the Ministère des Affaires Étrangères in Paris. On his way home, he had an attack of apoplexy and died in the early hours of March 23. His death occurred at a moment when he seemed on the point of achieving fame: 18 months earlier Balzac had published his great panegyric of *La Chartreuse de Parme* in the *Revue de Paris*; and Stendhal had just negotiated an advantageous contract with the *Revue des deux mondes* for a series of short stories. Only three people, including Mérimée, followed the coffin to the cemetery of Montmartre.

**Works.**—According to the official bibliographies, Stendhal is the author of 33 works, of which 19 were published posthumously. They can be divided into four broad groups: criticism, travel, autobiography, and fiction. He began his career as a critic with a book on music, *Les Vies de Haydn, de Mozart et de Métaïstase* (published 1814). It set the pattern for much that followed. He plagiarized shamelessly and without acknowledgment, but the stolen material was enlivened by his own, very individual, comments and anecdotes. This work appeared under the pseudonym of L. A. C. Bombet. Stendhal's use of pseudonyms—scholars claim to have counted 171—is one of his more curious psychological quirks. It may be connected with his fondness for using a strange mixture of French and rudimentary English as a primitive form of code when making subversive comments on the regime in his autobiographies and diaries. The most famous of his pseudonyms, however, was borrowed from the small Prussian town of Stendal or Stendhal. It was the birthplace of J. J. Winckelmann, the famous German art critic and, since it was first used for *Rome, Naples et Florence*, was probably intended as a tribute to him. That this was Stendhal's first book to enjoy a modest success may explain his retention of this pseudonym. After his *Histoire de la peinture en Italie* (1817), he turned from painting to literature in *Racine et Shakespeare* (two pamphlets, published 1823 and 1825), in which he defends Shakespeare at the expense of the author whom he himself regarded as the archclassic. He went back to music with his *Vie de Rossini* (1823). His posthumous collections of criticism include *Molière, la comédie et le rire* (1930), *Écoles italiennes de peinture* (1932), *Mélanges de littérature* (1933), and a series of articles known as the *Courrier anglais* contributed to English magazines between 1822 and 1839.

Most of his criticism was frankly hackwork. This is also true of the travel books: *Rome, Naples et Florence* (1817; 3rd edition 1826), *Promenades dans Rome* (1829), *Mémoires d'un touriste* (1838), *Pages d'Italie* (1932), and *Voyage dans le Midi de la France* (1854). He made some pretense of providing serious information, extracted from other people's guidebooks, but his artistic judgments were erratic, and he was not above giving eyewitness accounts of events that he had not in fact witnessed. Nevertheless, what gives the best pages their sparkle is the author's personal touch: the shrewd, humorous observations on men and manners, and a sprinkling of amusing, though often scabrous, stories.

There is an autobiographical element in all Stendhal's works, which are, in differing degrees, assaults on the central mystery of the self. He was preoccupied from his early years with the problem of self-knowledge, and his method of tackling it was often remarkable. In pages that remind us of Proust on involuntary memory he tells us, in *Henri Brulard*, that many of the incidents described came back to him only in the act of writing, that in putting down his memories of childhood he was able to visualize, for example, the exact positions of members of the family group at his mother's funeral. *Henri Brulard*, the *Journal* (5 volumes, 1888, 1923-34), *Souvenirs d'égotisme*, and the splendid correspondence, particularly the touching letters to his sister Pauline, together cover almost his entire life. The result is paradoxical. Although he has written more about himself than almost any other Frenchman, he remains one of the most elusive of famous novelists, and this has proved both a gift and a temptation to psychological biographers.

There are two books that do not fit easily into any of the four groups: a biography of Napoleon and a treatise on love. Although

he was a passionate admirer of Napoleon, his *Vie de Napoléon* (1929) is disappointing. The sources of *De l'amour* (1822) are partly literary, but the work is coloured by his own experiences, especially by the death of Mathilde Dembowska, the wife of a Polish general, whom he had loved in vain. It also contains the celebrated theory of "crystallization" (the growth of love compared to the dead branch of a tree that fell into a salt mine near Salzburg and became covered with sparkling crystals) that he was to use extensively in the novels.

Stendhal wrote five novels, two of them unfinished, and two volumes of *nouvelles*: *Chroniques italiennes* (1839) and *Romans et nouvelles* (1854). His novels can be fully appreciated only when regarded as parts of a single *œuvre*. The central figure in all of them is the *étranger* (or "outsider"), the "singular" individual who is at odds with the society in which he is living and who ends by disrupting it. Stendhal uses the word *imprévu* to convey the disconcerting effect his heroes have on other people: the quality that "singles them out," making them both outcasts and superior beings, members of that small elite, "the happy few," for whom he claimed to write. All are passionate lovers, but the young men regard falling in love as a misfortune that can never overtake them, and love simply as a means of satisfying their ambitions. It is part of the fascination of the novels to watch the process of "crystallization" taking place in spite of themselves, and their horror when they discover what has happened. Stendhal put much of himself into his characters. Whatever their birth, their outlook is essentially aristocratic, and, though professing "progressive" views, they share their creator's contempt for their fellow progressives. They also reflect the contradiction at the heart of what is known as "Beylisme." For Stendhal projected into his principal characters his own "pursuit of happiness," a happiness which is of its nature inaccessible. It is because he was aware of this that in the last analysis Stendhal's view of life, for all its gaiety and wit, is a tragic one.

"Politics in a novel," Stendhal was fond of saying, "is like a pistol shot at a concert. It is something crude from which it is nevertheless impossible to withhold our attention." All his own novels are political novels in this sense. In them he examined the sociopolitical scene at different moments between 1814 and 1840: *La Chartreuse de Parme* is a remarkable study of a miniature police state that has survived into the Napoleonic era; *Armance* and *Le Rouge et le noir* are criticisms of the situation in 1827–30; and *Lucien Leuwen* is a devastating exposure of political corruption under Louis Philippe. He was not content with examining the scene at different moments; he also examined it from different angles by choosing his heroes from different social classes. Fabrice in *La Chartreuse de Parme* is an aristocrat; the heroes of *Armance* and *Lucien Leuwen* come from the upper-middle class; Julien Sorel in *Le Rouge et le noir* is born into the proletariat but succeeds in rising out of his class and laying the foundations of what might have been a brilliant career by way of the army and the church (the "scarlet" and "black" of the title). In his last novel, *Lamiel*, he varied the pattern and chose a woman "outsider" who was a gangster's "moll."

**Assessment.**—"I have bought a ticket in a lottery," Stendhal once said; "the prize may be described as this: to be read in 1935." He had it firmly in mind that he was writing not for his contemporaries but for posterity and thought that he might enjoy a little posthumous fame about 1880. He did not have to wait so long. Taine's essay (see *Bibliography*) brought fame in the middle of the century, and Paul Bourget records that by the '80s he had become a cult among the young. The cult has grown into an industry; patient scholars have deciphered and published everything down to his laundry bills. A similar revolution has taken place in critics' views of his style. Once regarded as a novelist who "wrote badly," he is now hailed as a "prince of language" whose prose style is a model of clarity and concision.

Praise of Stendhal's psychological insight has been a commonplace of criticism since Taine, but it does not convey the full measure of his originality. In the "outsider" he created a new psychological type that altered the perspective of European fiction. Because he appeals through his characters to the "outsider,"

and the spirit of rebellion latent in all of us, he is for his admirers not so much a novelist whom they read, as a writer who has become, mysteriously, a part of their being.

**BIBLIOGRAPHY.**—*Editions, etc.*: *Oeuvres complètes*, including 10 vol. of correspondence, ed. by H. Martineau, 79 vol. (1927–37); *To the Happy Few*, selected letters trans. by N. Cameron (1952); *The Private Diaries of Stendhal*, ed. and trans. by R. Sage (1955); H. Cordier, *Bibliographie stendhalienne* (1914); V. del Litto, *Bibliographie stendhalienne, 1938–60*, 5 vol. (1945–62). Most of Stendhal's works have been translated.

**STENO, NICOLAUS** (NIELS STEENSEN or STENSEN (1638–1686), Danish naturalist, physician, and theologian, who made major early contributions to the science of crystallography and to the development of geologic theory, was born at Copenhagen on Jan. 10, 1638. He studied medicine at the University of Copenhagen, and in 1660 he went to Amsterdam and then to Leiden to continue his studies of anatomy. While at Amsterdam he discovered the parotid duct, also known as Stensen's duct. In 1664 he went to Paris, where he delivered a discourse on the anatomy of the brain that was printed in 1669. This paper was notable for its intelligibility and freedom from traditional interpretation. In 1665 he went to Florence, where he was appointed physician to the grand duke Ferdinand II.

Steno had time for travel and study in Italy and in 1669 published his geological observations in *De solido intra solidum naturaliter contento dissertationis prodromus* (translated into English with introduction by John G. Winter as *The Prodromus of Nicolas Steno's Dissertation Concerning a Solid Body Enclosed by Process of Nature Within a Solid* [1916]). In this short work he reported his discovery that quartz crystals that appear different from one another still have the same angles between corresponding faces (see *CRYSTALLOGRAPHY: Introduction*). He also was among the first to recognize fossils as remains of organisms and concluded that many rocks had formed in muddy marine or fresh waters. He rejected the idea that mountains grew, recognized the nature of volcanoes, and declared that some mountains had been shaped by running water. He attributed other mountains to "exhalations" and thought strata had been tilted and deformed as the roofs of great caverns collapsed. (See also *Geology: Development of the Science*.)

Steno became a Catholic in 1667 and soon abandoned science for religion. In 1676 he was made a bishop and was appointed apostolic vicar of northern Germany and Scandinavia. After a stormy career in Germany, he died at Schwerin in November 1686.

**STENOTYPY**, a system of machine-recorded shorthand in which letters or groups of letters phonetically represent syllables, words, phrases, and punctuation marks. The stenotype machine, commonly used in business offices and in court reporting, is virtually noiseless and can be operated at speeds of more than 250 words per minute. It is composed of letter keys, a space key, a correction key (\*), and a numeral bar that corresponds to the shift key on a typewriter. Four pairs of keys on the left side of the keyboard are initial consonants that print on the left side of a paper tape fed automatically through the back of the machine. Final consonants, five pairs of keys on the right, print on the right side of the tape. The four vowel keys centred below the consonants print in the centre of the tape.

The machine is operated with both hands, and several keys may be struck simultaneously to print a complete word with one

stroke. The fingers of the left hand strike initial consonants, and the left thumb strikes two of the vowels. The right hand controls final consonants and the remaining two vowels.

Combinations of letters are substituted for letters or groups of letters; e.g., TP on the left for an initial F sound, or, on the right, PL for a final M. Numerals are recorded by depressing the numeral bar and the key bearing the desired number.

In contrast with the variety of handwritten shorthand systems, stenotype recordings can be read by anyone familiar with the system, since it does not lend itself to individual modification.

**STEPHANITE**, which was an important ore of silver in the famous Comstock lode in Nevada, is a mineral consisting of silver, antimony, and sulfur,  $\text{Ag}_3\text{SbS}_4$ , containing 68.5% of silver. It occurs with other ores of silver in metalliferous veins. Under the name *Schwarzerz* (black ore) it was mentioned by G. Agricola in 1546. Stephanite has a hardness of 2.5 and is very brittle; the specific gravity is 6.3.

**STEPHEN, SAINT** (d. c. A.D. 36), the first Christian martyr, commemorated by the church on Dec. 26. He is the first named of the seven appointed for administrative duties when discord arose in the early Christian community about the neglect of Hellenistic widows (Acts 6-7). The choice of the men was determined by their endowment with the spirit and with wisdom, and their number corresponded with that of the seven elders chosen in Jewish synagogues. After their office had been suggested by the 12 apostles, who intended thus to be free to dedicate themselves to prayer and the ministry of the word, the seven were acclaimed by the whole community. Stephen, after performing "great wonders and signs," was accused by Hellenistic Jews before the Jewish high priest of blasphemy against the Temple and the Law. His speech of defense before the Sanhedrin served only to increase the fury of his accusers. Stressing the disobedience of the Jews, he traced God's guidance of them through their leaders Abraham, Isaac, Jacob, Joseph, Moses, and Joshua until they reached the Promised Land and Solomon built the Temple. He ended with a fierce denunciation of the Jews who had deviated from the way of God by resisting the Holy Spirit, persecuting the prophets, and murdering the Righteous One; i.e., Jesus. He then received a vision of God's glory, which enraged his accusers still more; they threw him out of Jerusalem and stoned him to death as he prayed God to forgive them. Saul (later the apostle Paul) was present, consenting to the execution. After Stephen's death his fellow officers were compelled to flee, whereas the apostles remained in Jerusalem unscathed; this suggests that the seven were at that time the leaders of the Christian community.

The Hellenistic Jews of Jerusalem, among whom Stephen himself probably originated, did not hold liberal views, as is frequently assumed, but were a particularly active and zealous force for orthodoxy. They were drawn to Jerusalem by their attachment to the holy site, as well as by an intensive messianic eschatology. For them the two things went together: the appearance of the Messiah was to take place in the Temple. At both these points they came into conflict with Stephen. Stephen must have passed on and intensified the prophecy of Jesus regarding the approaching destruction of the Temple. Furthermore, he was the first to proclaim the Second Coming of Jesus (until then the early church had spoken only of his assumption), linking this thought so closely with eschatological expectation as to exclude an earthly, political Messiah. This is the background to the trial of Stephen.

Stephen's speech as reported in Acts, like other speeches in ancient historical works, is not to be taken as an exact summary of what he actually said. It is even possible that it originally had nothing to do with Stephen but was an account of the history of salvation that the author of Acts wished to insert at this point. Or it may be a modified version of Stephen's views compiled after his death by those who wished to show that the Jews were to blame for his execution. Most of its contents are unimpeachable from the Jewish point of view.

The account of Stephen's death contains elements that imply a mob execution. These can be explained best as evidence that pressure was put on the Sanhedrin to stone him to death as a

blasphemer according to the Law, although by that time the right of capital punishment had passed from the Jewish authorities to the Roman procurator. For this reason it is likely that the execution took place after Pontius Pilate's recall (winter 36-37), during the vacancy in the procuratorship.

(E. BL.)

**STEPHEN**, the name of ten popes, sometimes numbered as nine, for reasons explained under *Stephen II*.

**ST. STEPHEN I** (d. 257), pope from 254 to 257, a Roman by birth, succeeded Lucius I. He is known principally from three controversies reported in the letters of St. Cyprian of Carthage. Stephen restored two Spanish bishops, accused of having "lapsed" under persecution (*libellatici*), and apparently he refused to depose Bishop Marcianus of Arles, accused of rigorism (Novatianism). Stephen also objected to the practice of rebaptizing heretics and threatened to excommunicate bishops in Africa (including Cyprian) and in Asia Minor unless they discontinued it. His death on Aug. 2, 257, almost coincided with a renewal of persecution under Valerian, but it is doubtful that he was martyred. His feast day is Aug. 2.

(F. X. G.)

**STEPHEN II** (d. 752), a Roman, was elected March 24, 752, and died a few days later, before having been consecrated. He is listed neither in the *Liber pontificalis* nor in the catalogue of the popes. His successor, who also took the name Stephen, is called both Stephen II and Stephen III. Hence the succession of the popes with the name Stephen is somewhat irregular.

**STEPHEN II (III)** (d. 757), pope from 752 to 757, was a deacon when chosen in March 752 to succeed Zacharias in place of Stephen II. The central act of his pontificate was to free the papacy from Byzantium and to ally it with the Franks. Twice he appealed to the Frankish king Pepin III the Short for assistance against the Lombard king Aistulf, who was trying to conquer all Italy. In 754, before anointing Pepin at Saint-Denis, he obtained from him, at Quierzy, the donation whereby Pepin promised to "restore" to the church the lands taken by the Lombards. In 756 Pepin subdued the Lombards and conferred on Stephen territory in the exarchate of Ravenna, the duchy of Rome, and the districts of Venetia and Istria. Thus the papal states were founded, independent of any temporal power, and Stephen became their first temporal sovereign. He died in April 757.

**STEPHEN III (IV)** (d. 772), pope from 768 to 772, was a Sicilian and a Benedictine. He succeeded Paul I on Aug. 7, 768. His pontificate was mainly occupied with reaction to the antipapal policies of the Lombard king Desiderius, who attempted an alliance with the Franks against Stephen. He died in February 772.

**STEPHEN IV (V)** (d. 817), pope from 816 to 817, succeeded Leo III in June 816. Immediately after his consecration he ordered the Romans to swear fidelity to the emperor Louis the Pious, whom he personally visited in the following August. His crowning of Louis at Reims solidified the alliance between the papacy and the Franks. He died in January 817.

**STEPHEN V (VI)** (d. 891), pope from 885 to 891, succeeded Adrian III. In his dealings with both East (Photius and the Slavonic church) and West (Ravenna and Bordeaux) he acted with the utmost independence and authority.

**STEPHEN VI (VII)** (d. 897), pope from 896 to 897, succeeded Boniface VI. His conduct toward the remains of Pope Formosus, which he exhumed, placed on trial, degraded, and desecrated, ended in his own imprisonment and strangulation in August 897.

**STEPHEN VII (VIII)** (d. 931), pope from 929 to 931, was born of a Roman family and as cardinal priest of Saint Anastasia was active in the administration of the Roman Church before his election to the papacy. The history of his pontificate is practically unknown. He died in February 931.

**STEPHEN VIII (IX)** (d. 942), pope from 939 to 942, was a Ro-

man elected on July 14, 939, to succeed Leo VII. His pontificate was dominated by the Roman prince Alberic, and Stephen had little opportunity for independent action. All his political efforts were directed toward the support of the last Carolingians. He died in October 942.

**STEPHEN IX (X)** (d. 1058), pope from 1057 to 1058, succeeded Victor II in August 1057, five days after the latter's death. His baptismal name was Frederick, and he was the brother of Godfrey, duke of Lorraine and marquis of Tuscany. Frederick, who had been raised to the cardinalate by Leo IX, acted for some time as papal legate at Constantinople and was with Leo in his unlucky expedition against the Normans. He showed great zeal in enforcing the law of clerical celibacy. During his pontificate the reform program became clearer, stronger, and more centralized. He died on March 29, 1058, at Florence.

See also **PAPACY**.

(R. E. McN.)

**STEPHEN** (c. 1097–1154), king of England from 1135 to 1154, was the third son of Stephen, count of Blois and Chartres, and Adela, daughter of William I, the Conqueror. He was brought up in the household of his uncle Henry I of England, from whom he received knighthood, the county of Mortain in Normandy, and the honours of Eye and Lancaster in England. In 1118 he renounced his claims to Blois and Chartres in favour of his elder brother Theobald, and by marrying Matilda, heiress of Eustace III, count of Boulogne, he acquired (1125) not only the county but also the large estates in England which went with it. In 1127 and again in 1133 he was among the English magnates whom Henry I persuaded or forced to take an oath of fealty to his daughter the empress Matilda (q.v.) as heir to the throne and to recognize the hereditary right of her son Henry of Anjou, the future Henry II. A woman ruler married to Geoffrey, count of Anjou, was doubly repugnant to the Normans, and a queen regnant was unprecedented in England. Consequently, on Henry I's death (Dec. 1, 1135), despite their oaths of fealty, many of the bishops and great lords of England gave Stephen a friendly welcome when he speedily crossed the Channel, and with the help of the citizens of London, of his brother Henry of Blois, bishop of Winchester, and of the enormously influential Bishop Roger of Salisbury, he was crowned at Westminster by Archbishop William of Canterbury (c. Dec. 22, 1135). The succession was confirmed by the pope and at Easter 1136 a great council was attended by a widely representative body of prelates and feudatories. But in April Stephen was forced to issue a charter of liberties which made far-reaching concessions to both church and laity. Moreover, to meet the threat of Scottish invasion, he conceded to Henry, son of King David I, Carlisle and the honour of Huntingdon, and he allowed his strongest potential opponent, Robert of Gloucester, half brother of Matilda, substantial concessions in return for his homage. In 1137 Stephen missed an opportunity, which never recurred, of winning Normandy from Matilda and her husband, and in 1138 Robert of Gloucester took up arms in her support. The Angevin cause, however, made little headway. Thanks partly to speedy reinforcements from Stephen, David of Scotland, supporting Matilda, was badly defeated at the Battle of the Standard (1138). But in 1139, at the instigation of the powerful Beaumont family, the king arrested Roger of Salisbury and his nephews, the bishops of Lincoln and Ely, and deprived them of office. Insofar as there was a governmental machine at this time it was in the hands of Bishop Roger and his family. Their disgrace and ill-treatment not only drew the church, including Stephen's own brother Henry of Winchester, over to the Angevin side, it also deprived the king of an effective exchequer.

**Civil War.**—The crisis was Matilda's opportunity. She came to England in September 1139 with Robert of Gloucester, and they quickly made the West Country an Angevin stronghold. It was characteristic of the chivalrous Stephen that instead of arresting Matilda when she landed, he gave her an escort to take her to Bristol, which her half brother made into an Angevin capital to rival royalist London. It was also in character that the king besieged a string of castles in turn without having the singleness of purpose to capture any of them. Holding the triangle formed by Bristol, Gloucester, and Wallingford, the Angevins proved hard to dislodge and early in 1141, finding an ally in Ranulf, earl of

Chester, they attacked and routed Stephen's forces at Lincoln. Stephen was made prisoner and Matilda's road to the throne lay open. But her arrogance offended Henry of Blois and also the citizens of London, from whom she had to flee. Stephen's mercenary captain William of Ypres returned to the fray and with Stephen's queen led a force which successfully routed the empress's supporters at Winchester (September 1141) and captured Earl Robert.

BY COURTESY OF KING'S COLLEGE, CAMBRIDGE, AND THE ROYAL ACADEMY OF ARTS

THE GREAT SEAL OF STEPHEN, SHOWING THE KING ON HORSEBACK AND FULLY ARMED

King and earl were soon exchanged (November) and gradually Stephen regained the upper hand. Oxford Castle fell to him in December 1142, Faringdon in 1145, and by 1147 when Earl Robert died Stephen seemed to be recognized as king over most of England from the Channel northward to the rivers Tyne and Ribble. North of that the king of Scots reigned supreme, despite his defeat in 1138.

**Weakness of Stephen's Rule.**—Nevertheless, Stephen failed utterly to keep the peace and dispense justice in those parts of England where he was recognized. He obtained the support of powerful lords only by lavish concessions, and he could not prevent the worst of them, such as Geoffrey de Mandeville, earl of Essex, from laying waste whole districts. It may be that life in many parts of England was not seriously disturbed during the "anarchy," but there is no doubt that scores of town and villages suffered dreadfully from the prevailing lawlessness. The monarchy itself suffered from Stephen's incompetence, losing ground both to the church and to the feudatories. Some great magnates made treaties of security with one another almost as though the king did not exist. Stephen was not always overruled. In 1140 he appointed his nephew William Fitz Herbert to the archbishopric of York and held his ground when the full weight of the reforming party in the church fiercely opposed the appointment. In spite of papal condemnation, Stephen's candidate ruled as archbishop for one year (1154). But the dispute finally ruptured any hope of reasonably good relations with the church, and Stephen failed to get his elder son Eustace crowned king in his own lifetime to ensure a peaceful succession.

**Last Years.**—In 1149 the 16-year-old Henry of Anjou made a serious but unsuccessful attempt to resume the Angevin military offensive. His next visit to England in 1153 was a much graver threat. Stephen was unable to prevent Henry, now duke of Normandy and Aquitaine, from traversing England from Bristol to the north Midlands and back to Wallingford, gaining en route numerous powerful adherents. A truce was arranged about the end of July, and Eustace's death in August made Stephen lose heart. A generous provision for the king's second son William made it possible for Stephen to reach firm agreement with Henry in November (Treaty of Winchester-Westminster, 1153) whereby Stephen would retain the throne till his death but Henry was recognized as his lawful heir. Stephen died at Dover on Oct. 25, 1154. Brave, generous, courteous, and not without energy, he had no political sense and lacked the ruthlessness essential for a strong king of 12th-century England. The *coup d'état* by which he won the throne is the most surprising episode in Stephen's career.

**BIBLIOGRAPHY.**—The chief authorities for the reign are the anonymous *Gesta Stephani*, *Regis Anglorum* and William of Malmesbury *Historia Novella*, both trans. ed. by K. R. Potter (1955); John of Hexham's continuation of Simeon of Durham, *Historia Regum*, ed. by T. Arnold, 2 vol. (1882–85); the authors collected in *Chronicles of the Reigns of Stephen, Henry II and Richard I*, ed. by R. Howlett (1884–89); the Peterborough version of the *Anglo-Saxon Chronicle*. These and other sources may be found in translation in *English Historical Documents*, vol. ii, ed. by D. C. Douglas and G. W. Greenaway (1951–55). For Stephen's charters see *Regesta Regum Anglo-Normannorum*, vol. iii, ed. by H. A. Cronne and R. H. C. Davis (forthcoming). See also A. L. Poole, *From Domesday Book to Magna Carta 1087–1216* (G. W. S. B.) 2nd ed. (1955).

**STEPHEN I** (SAINT STEPHEN; Hung. ISTVÁN) (977–1038), the first king of Hungary. A member of the Árpád dynasty, he was the son of the supreme chieftain Géza by his wife Sarolta. Brought up as a Christian, he had among his tutors the German priest Bruno, the Czech priest Radla, and an Italian knight, Theodatus of San Severino. In 996, he was married to Gisela, daughter of Duke Henry II of Bavaria. In 997 when his father died, the young Stephen was confronted by a formidable pagan insurrection in the country between the Drava River and Lake Balaton. Under the banner of St. Martin of Tours, whom he chose to be his patron saint, he routed the rebels at Veszprém (998). Immediately afterward he assumed the royal title. Doubt has been cast on the tradition (which seems to have started c. 1112 and was long developed) that in 1000 or 1001 he received a crown as a gift from Pope Sylvester II with a letter addressing him as "Apostolic King" because of his missionary zeal. The struggle against the pagan nobles long continued to preoccupy him, so that he adopted a peaceful policy toward the Byzantine and the Holy Roman emperors alike. Even so, he defended his kingdom successfully when the emperor Conrad II attacked it in 1030.

In organizing his kingdom Stephen adopted German examples. He introduced the county system, founded bishoprics and abbeys, made the building of churches mandatory, and established tithing. He promoted agriculture, safeguarded private property with strict laws, and organized a standing army. A ruling class was brought into existence, consisting of the chieftains who acknowledged his royal authority, the sheriffs at the head of the counties, foreign knights, and liegemen. In addition, there were serfs: peasants and shepherds, the conquered Slavs, and people captured by the Magyars during military expeditions abroad. This organization of a feudal state was the greatest achievement of Stephen's reign; but he also brought the Magyars into the European cultural community, while saving them from German conquest.

Stephen died in 1038 and was canonized in 1083. Stronghanded and resolute, a careful and adroit diplomat, broad-minded, tolerant, and well aware of the contemporary European situation, this outstanding statesman had founded the Hungarian nation.

See Bálint Hóman, *King Stephen the Saint* (1938). (GE. GR.)

**STEPHEN** (ISTVÁN BÁTHORY) (1533–1586), king of Poland from 1575, after being prince of Transylvania from 1571. He was born at Szilágyssomlyó (Simleu Silvaniei) on Sept. 27, 1533, the son of István Báthory, governor of Transylvania (q.v.) for the Habsburg king of Hungary, the future Holy Roman emperor Ferdinand I. After studies in Italy (at the University of Padua), he went in 1552 to Ferdinand I's court; but when John Sigismund Zápolya became prince of independent Transylvania in 1556, Báthory entered his service. Eventually he became commander in chief of the Transylvanian Army. Sent by John Sigismund to Vienna in 1563 to negotiate a rectification of the frontier between Habsburg Hungary and Transylvania, he was arrested by the future emperor Maximilian II, who was then about to become king of Hungary; a year later Maximilian released him. On May 25, 1571, despite Maximilian's objections, the Hungarians elected Báthory prince of Transylvania in succession to John Sigismund.

In 1575, rejecting Maximilian's candidature, the Polish nobility elected Stephen Báthory king of Poland in succession to Henry of Valois (who had fled in 1574 to become king of France as Henry III). Having secured the election of his brother Christopher as prince of Transylvania instead of himself, Stephen hastened to Cracow, married the Jagiello princess Anna (sister of Henry's predecessor Sigismund II of Poland), and, on May 1, 1576, was crowned king. Only Gdansk, which supported Maximilian's cause, offered armed resistance; it was finally reduced by blockade to submission (Dec. 8, 1577). Meanwhile Stephen had concluded a truce with the Turks (Nov. 5, 1577). The Russian tsar Ivan IV, however, had tried to exploit the Polish interregnum in order to obtain access for Muscovy to the Baltic Sea through Polish Livonia. In 1579, therefore, with supplies voted by the *sejm* (Diet) of Warsaw, Stephen began war against Ivan. After three campaigns (during which he besieged Pskov in 1581), he forced Ivan to cede Polotsk and Livonia to Poland under the truce of Jam Zapolski (Jan. 15, 1582).

In internal affairs, Stephen sought to promote the Counter-Reformation and to strengthen the royal power. This policy brought him into conflict with his subjects. Even so, he cherished the ambition of uniting Poland, Muscovy, and Transylvania in one great state; and he was preparing a new war against Muscovy (intended also as the prelude to a crusade against the Turks) when he died near Grodno, on Dec. 12, 1586.

See Jan Dabrowski et al., *Étienne Báthory, roi de Pologne, prince de Transylvanie* (1935). (ST. HE.)

**STEPHEN DUŠAN or DUSHAN** (c. 1308–1355), king of the Serbs from 1331 and tsar, or emperor, from 1346, was the son of Stephen Uroš III (see SERBIA: History). He fought against Stephen Kotromanić of Bosnia in 1329 and took part in the victorious Battle of Velbuzhd (Kyustendil) against the Bulgars in 1330 before being put on the throne, in his father's place, in 1331.

In war against the Byzantine Empire, Stephen in 1334 conquered Strumica, Prilep, Ohrid, and Kostur (Kastoria) and had advanced to the gates of Salonika when peace was made. In 1342, during the civil war in the Byzantine Empire, he and John Cantacuzenus (see JOHN VI, emperor) started a joint offensive against Constantinople. This alliance did not last long, and Cantacuzenus then approached the Turks, who as his allies advanced to Serrai (Ser) in Macedonia. Stephen, who was in possession of all Albania in the summer of 1345, took Serrai in September. Soon afterward he proclaimed himself "emperor of the Serbs and Greeks." Having elevated the Serbian archbishopric to the rank of patriarchate, he had himself crowned emperor at Skopje on Easter Day, 1346.

Epirus and Thessaly fell to Stephen in 1348, but he did not succeed in reconquering Hum (Hercegovina) from the Bosnians. Conscious of the menace of the Turks, he asked Pope Innocent VI to appoint him commander in chief of a crusade against them, but collaboration with the Holy See was interrupted by a Hungarian attack on Serbia in the summer of 1354.

Stephen's *Zakonik*, a code of law based on the Byzantine model (with some regulations taken over from earlier Serbian rulers) and valid for his whole empire, was promulgated at Skopje in 1349; addenda were promulgated at Serrai in 1354.

Stephen died on Dec. 20, 1355. He had given Serbia the widest frontiers in all its history. (M. A. P.)

**STEPHEN THE GREAT** (d. 1504), prince or *voivode* of Moldavia from 1457, a figure of European importance because of his long resistance to the Ottoman Turks. The son of Prince Bogdan II (d. 1451), he succeeded his uncle, Prince Peter III, in 1457, four years after the fall of Constantinople to Sultan Mohammed II.

Mohammed launched an attack on Moldavia, but Stephen heavily defeated the invaders at Vaslui in 1475. For this success he received a letter of praise from Pope Sixtus IV and was hailed by the Polish chronicler Jan Dlugosz as "the first of the princes of the world to win so brilliant a victory over the Turks." There followed another victory at Valea Albă (1476) and, after some reverses in 1484–85, a further victory at Scheia (1486). The Turkish menace, and his concern for Moldavia's independence, motivated Stephen's negotiations with Matthias Corvinus, king of Hungary, and with Casimir IV, king of Poland. These culminated in alliances, which, however, brought no adequate help, material or military. Finally, in 1503, recognizing the economic and military superiority of Turkey, Stephen concluded a treaty with Sultan Bayazid II whereby Moldavia conserved its independence at the cost of paying an annual tribute to the Turks.

Stephen's internal policy was designed to establish a centralized state with the support of the freeholders, the townspeople, and the petty boyars. He promoted commercial and cultural development; his reign saw the building of the fortresses and market towns at Suceava, Baia, and Scheia, and also of many monasteries in the architectural style characteristic of Moldavia, as well as the writing of the Bistrița and Putna chronicles.

**STEPHEN, SIR JAMES FITZJAMES** (1829–1894), English judge, law reformer and historian whose work in the codifying of criminal law was of wide and lasting influence, was born in London on March 3, 1829. He was the son of James Stephen, for

many years undersecretary of state for the colonies, and an elder brother of Leslie Stephen, English philosopher and critic. Stephen was educated at Eton, London university and Trinity college, Cambridge. He was called to the bar in 1854, was made recorder of Newark in 1859, and became queen's counsel in 1868. In his early years at the bar, Stephen became one of the leading controversial publicists of his day. His miscellaneous writings, which encompass a wide range of topics, appeared frequently in such journals as the *Pall Mall Gazette* and the *Saturday Review*. Stephen's intellectual position may, in some respects, reflect the utilitarian tradition; but his thought was of a highly individual cast, and he was in no sense the disciple of any school. In 1863 he published his *General View of the Criminal Law of England*, a work of great importance, representing the first attempt since Blackstone to give systematic statement to the principles of English criminal jurisprudence. Ten years later, in reply to J. S. Mill's *On Liberty*, Stephen published *Liberty, Equality, Fraternity*, a work antidemocratic in tendency and displaying defects of expression and argument, which, nevertheless, remains one of the important statements of the conservative political philosophy.

In 1869 Stephen accepted the post of legal member of the viceroy's council in India and, like Macaulay and Sir Henry Maine before him, became engrossed in the reform and recodification of Indian law. He returned to England in 1872 and almost immediately became identified with the movement to codify the criminal law of England. His *Digest of the criminal law* (1877) was enthusiastically received. He was the principal draftsman of the Indictable Offences bill, which was, in effect, a criminal code. Because of powerful opposition, the bill was never introduced in parliament. Although failing of their immediate objectives, Stephen's efforts influenced the drafting of legislation in the nations of the British commonwealth, and, even today, are consulted in attempts to reformulate the criminal law of English-speaking countries. In 1883 Stephen published his great work, *History of the Criminal Law of England*. Although dogmatic in tone, often deficient in the critical handling of sources, and in many respects incomplete, the work represents a remarkable achievement which, on the whole, has never been surpassed.

In 1879 Stephen became a judge in the queen's bench division of the high court. He resigned in 1891, after a breakdown, and received a baronetcy in recognition of his services. He died in Ipswich on March 11, 1894. A selection of his letters, edited by his daughter, Caroline Emilia Stephen, was published in 1907.

**BIBLIOGRAPHY.**—Sir Leslie Stephen, *Life of Sir James Fitzjames Stephen* (1895) with bibliographical appendix, is one of the outstanding biographies in the English language; a shorter account by the same author will be found in the *Dictionary of National Biography*. See also Sir C. P. Ilbert, "Sir James Stephen as a Legislator," *Law Quart. Rev.*, x, 222; L. Radzinowicz, *Sir James Fitzjames Stephen*, Selden Society Lecture (1957). (F. A. A.)

**STEPHEN, SIR LESLIE** (1832–1904), English critic, man of letters and first editor of the *Dictionary of National Biography*, was born in London on Nov. 28, 1832, into a distinguished intellectual family. His grandfather was a member of the Clapham sect, his father a fine colonial servant, his brother a great criminal lawyer and Anglo-Indian administrator; the Venns and Diceys were his first cousins. He was educated at Eton, at King's college, London, and at Trinity hall, Cambridge, where he was elected to a fellowship in 1854 and became junior tutor in 1856. He won fame as a rowing coach and inaugurated the Oxford and Cambridge athletics contest; he also tried unsuccessfully to reform the outdated university curriculum. He had been ordained in 1855, but his philosophical studies, combined probably with the controversy that followed the publication of Charles Darwin's *Origin of Species* (1859), caused him to lose his faith; in 1862 he resigned his tutorship and two years later left Cambridge to live in London.

Through his brother, James Fitzjames, a contributor to the *Saturday Review*, Stephen gained an entry to the literary world, contributing to many periodicals. In politics he was a radical and supported the North during the American Civil War, and his articles in defense of agnosticism were republished in *Essays on Freethinking and Plainspeaking* (1873) and *An Agnostic's Apology*

(1893). In 1871 George Smith offered him the editorship of the *Cornhill*, for which he wrote literary criticism later republished in the three series of *Hours in a Library* (1874–79). Stephen was the first serious critic of the novel and his work still deserves consideration by historians of literary criticism. Thomas Hardy, R. L. Stevenson, Edmund Gosse and Henry James were among those whom Stephen, as an editor, encouraged. After 11 years he resigned but continued to write for periodicals. *Studies of a Biographer* (4 vol., 1898–1902) and *Social Rights and Duties* (1896) contain the best of this work. He also wrote a short book on *Hobbes* (1904) and his Ford lectures, *English Literature and Society in the Eighteenth Century* (1904), were pioneer work in the sociological study of literature.

His greatest learned work was his excellently written *History of English Thought in the Eighteenth Century* (1876). *The English Utilitarians* (1900) was less compact and successful though it is still a useful source. His philosophical contribution to rationalist tradition, *Science of Ethics* (1882), attempted to wed evolutionary theory to ethics. His most enduring bequest to posterity is the *Dictionary of National Biography*, of which he edited the first 26 volumes and to which he contributed many biographies. In recognition of this service to letters he was created knight commander of the Bath in 1902 and received other honours.

Stephen was a leader among Victorian mountaineers and was president of the Alpine club (1865–68) and editor of the *Alpine Journal* (1868–71). Some of his more famous climbs are recorded in *The Playground of Europe* (1871). He was also the leader of "The Tramps," a club of intellectuals who enjoyed taking 30-mi. Sunday walks.

Stephen was highly respected in intellectual society and remembered for many acts of kindness to his friends. He was formidable in appearance, dispassionate in judgment and the enemy of whatever he considered to be cant or wilful obscurity which was designed to conceal the truth. He was shy and given to silence, the more so after the death in 1875 of his first wife Minny, the second daughter of Thackeray. In 1878 he married Julia Jackson, the widow of Herbert Duckworth, and among their four children were the painter Vanessa Bell and the novelist Virginia Woolf. He died in London on Feb. 22, 1904.

**STEPHENS, ALEXANDER HAMILTON** (1812–1883), vice-president of the Confederate States during the American Civil War, was born in Wilkes (now Taliaferro) County, Georgia, on Feb. 11, 1812. In 1829 Stephens was sent by the Georgia Educational Society to Franklin College (University of Georgia), where he graduated in 1834. After teaching in rural schools for approximately a year and a half, he read law and was admitted to the bar in 1834.

BY COURTESY OF THE NATIONAL ARCHIVES

STEPHENS

In 1836 he was elected to the Georgia House of Representatives after a campaign in which he attacked the doctrine of nullification and opposed all extralegal steps against the abolitionists. He was annually reelected until 1841; in 1842 he was elected to the state Senate, and in the following year, on the Whig ticket, to the national House of Representatives. In this latter body he urged the annexation of Texas, chiefly as a means of achieving more power for the South in Congress. He vigorously supported the Compromise of 1850 and continued to act with the Whigs of the North until they, in 1852, nominated Gen. Winfield Scott for the presidency without Scott's endorsement of the compromise. In 1854 Stephens helped secure passage of the Kansas-Nebraska Bill.

He strongly opposed secession, but when Georgia seceded he followed his state and was elected vice-president of the Confederacy.

Throughout the war, Stephens was so concerned about states' rights and civil liberty that he opposed the exercise of extra-constitutional war powers by Pres. Jefferson Davis lest the freedom for which the South was fighting should be destroyed. His policy was to preserve constitutional government in the South and strengthen the antiwar party in the North by convincing it that the Lincoln administration had abandoned such government; to the same end he urged, in 1864, the unconditional discharge of Federal prisoners in the South. Stephens headed the Confederate commission to the peace conference at Hampton Roads, Va., in February 1865. In the following May, after the fall of the Confederacy, he was arrested at his home and taken to Fort Warren, in Boston Harbour, where he was confined until Oct. 12. In 1866 he was elected to the U.S. Senate but was not permitted to take his seat. He was a U.S. representative (1873-82) and governor of Georgia in 1882-83, dying in office, at Atlanta, on March 4, 1883.
